Box 231, Santo, Vanuatu; and <sup>4</sup>Institut Agronomique néo-Calédonien (IAC), P.O. Box 73, 98890 Païta, New Caledonia

- *Premise of the study:* Using next-generation sequencing technology, new microsatellite loci were characterized in *Artocarpus altilis* (Moraceae) and two congeners to increase the number of available markers for genotyping breadfruit cultivars.
- *Methods and Results:* A total of 47,607 simple sequence repeat loci were obtained by sequencing a library of breadfruit genomic DNA with an Illumina MiSeq system. Among them, 50 single-locus markers were selected and assessed using 41 samples (39 *A. altilis*, one *A. camansi*, and one *A. heterophyllus*). All loci were polymorphic in *A. altilis*, 44 in *A. camansi*, and 21 in *A. heterophyllus*. The number of alleles per locus ranged from two to 19.
- *Conclusions:* The new markers will be useful for assessing the identity and genetic diversity of breadfruit cultivars on a small geographical scale, gaining a better understanding of farmer management practices, and will help to optimize breadfruit genebank management.

**Key words:** *Artocarpus altilis*; breadfruit; high-throughput sequencing; Illumina; microsatellites; Moraceae.

Breadfruit (*Artocarpus altilis* (Parkinson) Fosberg, Moraceae) is a multipurpose tree crop with a great potential for increasing food security, thanks to its nutritious and starchy fruit (Ragone, 1997). In the Pacific Islands, it is a traditional staple crop, typically grown in backyards and small holdings. Breadfruit's wild progenitor, *A. camansi* Blanco, is a native species of New Guinea where the first steps of breadfruit domestication occurred. Pacific seafarers migrated eastward carrying breadfruit in the form of seeds or cuttings (Kirch, 1997). Other events, such as accumulated somatic mutations and meiotic defects in diploid genomes of *A. altilis*, resulted in seedless triploid cultivars that predominate in eastern Polynesia (Zerega et al., 2004). Witherup et al. (2013) developed simple sequence repeat (SSR) loci from microsatellite-enriched libraries and validated 25 of them across a large number of *A. altilis* cultivars, wild congeners, and relatives. This traditional SSR isolation approach is a cost- and labor-intensive process that requires repeat enrichment, cloning, and Sanger sequencing. Next-generation sequencing (NGS) technologies allow a good coverage of large genomes, cost-effective identification, and rapid characterization of hundreds of SSRs in nonmodel organisms without previous genomic resources (Zalapa et al., 2012). Gardner et al. (2015) used

this technology to develop 15 chloroplast SSRs from transcriptome data of *Artocarpus* spp. We report here on the development and validation of a new set of 50 nuclear SSR markers for breadfruit and related species using NGS Illumina technology.

### METHODS AND RESULTS

Leaf fragments of 41 samples of *A. altilis* (33 diploids, six triploids), *A. camansi*, and *A. heterophyllus* Lam. originating from Vanuatu, New Caledonia, French Polynesia, Tonga, Samoa, and the Mariana Islands were collected from living trees conserved in field genebanks (Appendix 1) and stored in a drying agent (silica gel) at room temperature. DNA was extracted according to the mixed alkyl trimethylammonium bromide (MATAB) protocol described by Risterucci et al. (2000). Total genomic DNA isolated from *A. altilis* 'Novan' (sample VUT002; National Center for Biotechnology Information [NCBI] BioSample SAMN04508170) was used to generate the library with the Nextera DNA Library Preparation Kit (Illumina, San Diego, California, USA) according to the manufacturer's protocol. Paired-end sequencing was carried out at the Grand Plateau Technique Régionale platform (Montpellier, France; <http://www.gptr-lr-genotypage.com>) on an Illumina MiSeq system using the MiSeq Reagent Kit version 3 (2 × 300 bp). The sequences were assembled using ABySS software (Simpson et al., 2009). SSRs were detected using MISA Perl script (Thiel et al., 2003) with search parameters set as follows: at least five repeats for dinucleotide motifs, four repeats for trinucleotide motifs, and three repeats for tetra-, penta-, and hexanucleotide motifs. Primers were designed with Primer3 software using standard settings (Rozen and Skaletsky, 1999). A total of 2,341,465 paired-end sequences were assembled into 1,281,784 contigs. Among them, 115,499 contigs exhibited at least one microsatellite locus and enabled us to define PCR primers on 46,504 contigs, totaling 47,607 SSR loci (Appendix S1). The cumulative length of these contigs was around 15.5 Mb, totaling approximately 6% of the sequence length generated in this study. Raw sequencing data were submitted to the NCBI Sequence Read Archive (accession SRP070931) under BioProject PRJNA312880.

<sup>1</sup>Manuscript received 23 February 2016; revision accepted 14 April 2016.

The authors thank H. Vignes for assistance with the construction of the library, X. Argout for assistance with bioinformatics analysis, C. Hamelin for data curation of TropGeneDB, X. Perrier for helpful comments on the manuscript, and P. Biggins for editorial input.

Note:  $T_a$  = annealing temperature.

<sup>a</sup>Additional information can be found in TropGeneDB, a multitropical crop information system, hosted by the SouthGreen bioinformatics platform (<http://tropgenedb.cirad.fr/>).

As a first step, 96 loci were selected according to the following criteria for motif type, repeat length, and amplicon size. We firstly excluded dinucleotide motifs, because these are prone to enzyme slippage during amplification, which may make allele designation difficult (Guichoux et al., 2011). Only perfect motifs were selected, as they are more likely to follow the stepwise mutation model. We selected loci with lengths of 11 to 16 repeats, as recommended by van Asch et al. (2010). Lastly, we selected loci with amplicon sizes ranging from 100 to 400 bp to facilitate the construction of multiplex sets.

The 96 primer pairs were then tested for amplification with a subset made up of four samples (two *A. altilis*, one *A. camansi*, and one *A. heterophyllus*). Only 15 failed to amplify. The remaining 81 primer pairs were classified according to their polymorphism and the overall quality of the profile. Among them, we chose to select only 50 polymorphic single-locus markers with no ambiguity in allele size determination (Table 1). These 50 SSRs were assessed using the 41 samples listed in Appendix 1. For comparison, we genotyped the same samples with 18 SSRs developed by Witherup et al. (2013). PCR reactions were performed in a solution A (25- $\mu$ L total volume) containing 2.5  $\mu$ L of PCR buffer (10 mM Tris-HCl, 50 mM KCl, 2 mM MgCl<sub>2</sub>, 0.001% glycerol), 2.5  $\mu$ L of dNTP (Jena Bioscience GmbH, Jena, Germany), 0.25  $\mu$ L of MgCl<sub>2</sub>, 0.2  $\mu$ L of 10  $\mu$ M forward primer with an M13 tail at the 5′-end (5′-CACGACGTTGTA-AAACGAC-3′), 0.25  $\mu$ L of 10  $\mu$ M reverse primer, 0.25  $\mu$ L of fluorescently labeled M13-tail (6-FAM, NED, VIC, or PET [Applied Biosystems, Foster City, California, USA]), 0.1 units of *Taq* DNA polymerase (Sigma-Aldrich, St. Louis, Missouri, USA), 5  $\mu$ L of template DNA (5 ng/ $\mu$ L), and 14  $\mu$ L of H<sub>2</sub>O. The PCR conditions were as follows: an initial denaturation at 94°C for 5 min; 30 cycles at 94°C for 45 s, 55°C for 45 s, and 72°C for 1 min; and a final extension at 72°C for 10 min. PCR products were pooled in a solution B containing: 2  $\mu$ L of 6-FAM, 2  $\mu$ L of VIC, 2.5  $\mu$ L of NED, and 3.5  $\mu$ L of PET. From this solution B, a volume of 4  $\mu$ L was taken and added to 10  $\mu$ L of Hi-Di formamide and 0.12  $\mu$ L of GeneScan 600 LIZ Size Standard and analyzed on an ABI 3500xL Genetic Analyzer (Life Technologies, Carlsbad, California, USA). Alleles were

scored using GeneMapper version 4.1 software (Applied Biosystems). Basic statistics were computed using PowerMarker software (Liu and Muse, 2005).

Of the 50 loci assessed, all amplified and were polymorphic in *A. altilis*, 44 in *A. camansi*, and 21 in *A. heterophyllus*. The number of alleles per locus ranged from two (mAaCIR0167) to 19 (mAaCIR0121), with an average of seven alleles per locus (Table 2). When genotyping the samples with 18 of the SSRs developed by Witherup et al. (2013), we obtained similar results, but with a smaller number of alleles, ranging from one (MAA3) to 10 (MAA156) with an average of six alleles per locus (Appendix 2).

The Hardy–Weinberg equilibrium (HWE) test was only performed on diploids from Vanuatu and revealed that 20 of the new SSRs exhibited significant deviation from HWE (Table 2). This is not surprising as we did not sample populations but cultivated varieties, most of them clonally propagated and maintained in the form of a few trees planted in backyards or gardens. In the triploids, we calculated the percentage of heterozygous individuals and gave the number of individuals harboring one, two, or three alleles for each microsatellite locus. For 60% of the microsatellite loci, we observed unambiguous genotypes (i.e., with three alleles), ranging from one individual (mAaCIR0178) to five individuals (mAaCIR0080). Fifty percent of the loci were highly informative with a polymorphism information content value (PIC; Botstein et al., 1980), calculated on diploid data, greater than 0.7; only seven had a PIC less than 0.5, with a minimum value of 0.29 for mAaCIR0078. Although less informative, this latter category of loci may have characteristics, such as private alleles, useful for detecting admixture between species.

## CONCLUSIONS

These 50 new nuclear SSR loci will be useful for assessing the identity and genetic diversity of breadfruit cultivars on a

TABLE 2. Continued.

Note: A = number of alleles; *H<sub>e</sub>* = expected heterozygosity; *H<sub>o</sub>* = observed heterozygosity; HWE = Hardy–Weinberg equilibrium; Obs = number of observations; PIC = polymorphism information content value, calculated on diploid data, as described by Botstein et al. (1980).

<sup>a</sup>Including the 19-bp M13-tail.

<sup>b</sup>To test HWE, a  $\chi^2$  goodness-of-fit method was used; \* = significant at  $P < 0.05$ , ns = no significant deviation from HWE.

<sup>c</sup>Due to allele ambiguity in the triploids, the *H<sub>e</sub>*:*H<sub>o</sub>* ratio is replaced by the percentage of heterozygous genotypes.

<sup>d</sup>Number of triploid individuals with three, two, or one allele(s).

small geographical scale and for gaining a better understanding of farmer management practices (seed or vegetative propagation methods, exchanges, and dispersal). They will help to optimize the management of national genebanks by identifying duplicates and guiding future collecting activities. Of the 47,607 SSR loci identified, a very large number of additional markers could be further developed to address future research needs (genetic mapping, QTL, and association studies).

Note: — = not available.

<sup>a</sup>The study was conducted with 41 living accessions forming two subsets of the collections of the Vanuatu Agricultural Research and Technical Centre (VARTC) and the Institut Agronomique néo-Calédonien (IAC). The VARTC genebank is located on the island of Santo, Vanuatu (15.453°S, 167.184°E). The 27 VARTC accessions (VUT label) were collected during two surveys conducted across the Vanuatu archipelago in 2004–2005 by Navarro et al. (2007) and in 2009 by Mies (no published data) with the support of the Pacific Plant Genetic Resources Network under the auspices of the Pacific Community (SPC). The 14 IAC accessions are conserved at the research stations of Saint-Louis (22.232°S, 166.538°E) and Pocquereux (21.731°S, 165.886°E) in New Caledonia. They comprise six accessions of *A. altilis*, one *A. heterophyllus*, and one *A. camansi*, all of them collected in New Caledonia, and six seedless cultivars sent to IAC by the National Tropical Botanical Garden of Hawaii (NTBG) from the Kahanu Garden, Maui Island in 1999. Leaf fragments were collected from living trees conserved in the field genebanks and stored in a drying agent (silica gel) at room temperature before performing DNA extraction.

\* Sample used to generate the genomic library (NCBI BioSample SAMN04508170).

APPENDIX 2. Genetic properties of 18 SSR markers developed by Witherup et al. (2013) tested on *Artocarpus altilis* and congeners.

Note: A = number of alleles;  $H_e$  = expected heterozygosity;  $H_o$  = observed heterozygosity; HWE = Hardy–Weinberg equilibrium; Obs = number of observations; PIC = polymorphism information content value, calculated on diploid data, as described by Botstein et al. (1980).

<sup>a</sup>Including the 19-bp M13-tail.

<sup>b</sup>To test HWE, a  $\chi^2$  goodness-of-fit method was used; \* = significant at  $P < 0.05$ , ns = no significant deviation from HWE.

<sup>c</sup>Due to allele ambiguity in the triploids, the  $H_e : H_o$  ratio is replaced by the percentage of heterozygous genotypes.

<sup>d</sup>Number of triploid individuals with three, two, or one allele(s).
