ABSTRACT—A new genus and species of pycnodontiform fishes, Grimenodon aureum, from marginal marine, marine-brackish lower Toarcian (Harpoceras exaratum ammonite subzone) clay deposits of Grimmen in northeastern Germany is described. The single specimen represents a diagnostic left prearticular dentition characterized by unique tooth arrangement and ornamentation patterns. Grimenodon aureum, gen. et sp. nov., is the second unambiguously identified pycnodontiform species from the Early Jurassic, in addition to Eomesodon liassicus from the Early Lower Jurassic of western Europe. We also report an indeterminate pycnodontiform tooth crown from the upper Pliensbachian (Pleuroceras apyreum ammonite subzone) of the same site. The material expands the Early Jurassic range of pycnodontiforms significantly northwards and immediately following the onset of the Toarcian Oceanic Anoxic Event (T-OAE) in the marginal marine ecosystems south of the Fennoscandian Shield. Moreover, the new records indicate that the Early Jurassic diversity of pycnodontiform fishes was greater than previously assumed and probably equaled that of the Late Triassic. Therefore, it is hypothesized that the Triassic-Jurassic mass extinction event did not affect pycnodontiform fishes significantly. Micro-computed tomography was used to study the internal anatomy of the prearticular of Grimenodon aureum, gen. et sp. nov. Our results show that no replacement teeth were formed within the tooth-bearing bone but rather were added posteriorly to functional teeth.

INTRODUCTION

Extinct pycnodontiform fishes (the ‘pycnodonts’), which are a morphologically and ecologically distinctive group of basal neopterygians (Nursall, 1996b, 1999, 2010; Arratia, 1999; Poyato-Ariza, 2015) are characterized inter alia by a very specific heterodontous dentition consisting of chisel or styliform grasping teeth on the paired premaxillae and dentalosplenials and, generally, densely arranged molariform teeth on the unpaired vomer in the upper jaw and the paired prearticulaires in the lower jaw. The maxillae are edentulous. Vomerine and prearticular teeth form an effective crushing dentition, indicating durophagous feeding habits in a wide range of pycnodontiforms (Kriwet, 2001a). The robust dentate jaw elements and isolated teeth are the most common remains of pycnodontiforms in the fossil record, occurring nearly worldwide in most marine and even brackish water–to freshwater-influenced deposits of Mesozoic and Palaeogene ages (e.g., Longbottom, 1984; Poyato-Ariza et al., 1998; Kriwet, 1999; Poyato-Ariza and Bermúdez-Rochas, 2009; Martin-Abad and Poyato-Ariza, 2013). Disarticulated or articulated skeletons, conversely, are comparably rare. So far, ca. 700 species have been described, belonging to more than 45 genera (Kriwet, 2001c, 2005); only about 80 species are known from disarticulated or articulated skeletons. All remaining species are based on isolated dentitions or even teeth.

Teeth and jaws are important functional structures but also offer significant taxonomic and evolutionary features for characterizing fishes (e.g., Fink, 1981; Lauder and Liem, 1983; Casciotta and Arratia, 1993). Nevertheless, controversial issues concerning the formation of dentitions and the taxonomic importance of tooth morphologies and arrangements in pycnodontiform fishes still prevail and detailed dental information often is omitted from species or genus diagnoses in more recent studies (e.g., Thurmond, 1974; Nursall, 1996; Poyato-Ariza and Wenz, 2005; Ebert, 2016). Therefore, knowledge of pycnodontiform tooth structures and dentitions is strongly biased towards those found isolated rather than those preserved in articulated skeletons. Additionally, Poyato-Ariza (2003) argued that pycnodontiform dentitions do not present useful character sets for phylogenetic analyses. The validity of many taxa consequently remains ambiguous. Nevertheless, Longbottom (1984), Kriwet (1999, 2005,
2008), Poyato-Ariza and Bermúdez-Rochas (2009), and Shimada et al. (2010), among others, demonstrated that the morphology and arrangement of teeth on the vomer and prearticulans in pycnodontiform fishes provide unique combinations of characters and even allow identifying autapomorphic traits for taxon assignment and establishing reliable diagnoses. The importance of recognized autapomorphic characters in phylogenetic analyses, however, needs to be tested.

The oldest remains of pycnodontiform fishes, which comprise both complete skeletons and isolated dentitions, are known from Norian (Late Triassic) marine deposits of the northern Tethys margin (what is now northern Italy and Austria) (Gorjanović-Kramberger, 1905; Tintori, 1981) and from epicontinental sea deposits of Belgium and Luxembourg (Delsate and Kriwet, 2004). They persisted into the middle Eocene when they supposedly were replaced by spiny teleosts (Friedman, 2010; Goatley et al., 2010). During the Late Jurassic, pycnodontiform fishes seemingly rapidly diversified, reaching their highest taxonomic diversity and morphological disparity in the Late Cretaceous (Kriwet, 2001b; Poyato-Ariza and Martín-Abad, 2013; Marrama et al., 2016). The Early and Middle Jurassic fossil record of pycnodontiforms in the aftermath of the Triassic-Jurassic mass extinction event, conversely, is extremely scarce. So far, a single species and at least 12 nominal species have been described from the Early and Middle Jurassic, respectively (see also below). Most of these species are represented by isolated vomerine and prearticular dentitions only, rendering their identification difficult. Consequently, most of the Middle Jurassic pycnodontiform species are dubious and in need of revision.

Here, we present new dental remains of pycnodontiforms from the Early Jurassic of Europe, including a new genus and species that provides evidence that the taxonomic diversity, and probably morphological disparity, of pycnodontiform fishes after the Triassic-Jurassic extinction event was greater than previously assumed.

**GEOLOGICAL AND STRATIGRAPHIC SETTING**

Although laterally persistent in northeastern Germany, outcrops of Mesozoic strata are rare (e.g., Katzung, 2004). Early Jurassic strata only crop out in the abandoned open-cast clay pits of Grimmen and Dobbertin (Fig. 1A), both representing parautochthonous successions of upper Pliensbachian to lower
Toarcian marine sediments that were glacially dislocated during Pleistocene ice advances (see Ernst, 1967, 1991, 1992; Ansorge and Obist, 2015; Ansorge and Grimmberger, 2016).

The fossil fish material that forms the focus of the present study encompasses two pycnodontiform specimens, GG 437 and MV 202615, that were recovered from upper Pliensbachian and lower Toarcian strata, respectively, of the Grimmen clay pit (Fig. 1B).

Paleogeographically, the late Early Jurassic succession exposed in the Grimmen clay pit was deposited at the north-eastern edge of the North German Basin (NGB), which was one of the many sub-basins that covered large areas of central and western Europe during Early Jurassic times (Fig. 1C), referred to as the Central European Epicontinental Basin (CEB) (Röhl and Schmid-Röhl, 2005). The litho- and biostratigraphy of the exposed succession have been described in detail by Ernst (1967, 1991), Prauss (1996), and Ansorge (2007). The upper Pliensbachian interval of Grimmen is represented by un lithified fine-grained sand containing thin beds of silt, and subordinate lenticular streaks of clay, as well as laterally limited fine- to coarse-grained, bioclastic-rich sand bodies, which are indicative of local accumulations generated by current activity, suggesting a shallow-marine deltaic depositional environment (Ernst, 1967, 1991; Ernst in Gründel, 1999). Pyrite and carbonate concretions, less commonly siderite concretions, are present. The fauna is rich in marine invertebrates, comprising ammonites, bivalves, gastropods, brachiopods, scaphopods, echinoderms, ostracods, and foraminifers (Ernst, 1967, 1991; Herrig, 1969a, 1969b; Kutcher, 1988; Gründel, 1999; Buchholz, 2012). These beds also yielded a diverse vertebrate fauna, including isolated actinopterygian and chondrichthyan remains (Buchholz, 2012; this paper).

Biostratigraphically, the sandy interval has been correlated with the apyrenum subzone (lower spinatum zone) based on ammonite evidence (Ernst, 1991; Buchholz, 2012). The Pliensbachian-Toarcian transition is omitted due to a hiatus, probably caused by erosion and non-deposition (see Röhl and Schmid-Röhl, 2005). Therefore, the uppermost spinatum zone (hawskerense subzone) and probably much of the lower Toarcian tenuis-costatum zone (paltum to clevelandicum subzone) are absent (Ernst, 1991). The lower Toarcian interval shows a retrogradational stratal pattern, consisting of fine-grained sands that pass upwards into black bituminous, laminated silty clays referred to the latest tenuis-costatum zone (semicelatum subzone), and pure clays containing fossiliferous concretions, used to date the clay deposits to the lower falciferum zone (elegantatum to exaratum subzone). The clay interval is assigned to the traditionally called ‘Green Series’, which reaches thicknesses of several tens of meters in northeastern Germany (Schumacher and Sonntag, 1964; Stoermer and Wienholz, 1965; Lehmkühl, 1970), and markedly differs from the time-equivalent black bituminous shales and marlstones known from more basinal sections of the CEB (e.g., Jenkyns, 1988; de Graciansky et al., 1998; Röhl and Schmid-Röhl, 2005).

Clay deposits referred to the ‘Green Series’ crop also out in the abandoned Dobbertin clay pit. However, unlike those exposed at Grimmen, these clay deposits can solely be dated to the falciferum zone on the basis of current data (Ansorge, 2003; Ansorge and Obist, 2015). Given the tectonic disturbances that took place during glacial dislocation, the original thicknesses of the ‘Green Series’ clay deposits of both Grimmen and Dobbertin cannot be firmly determined.

Fossils originating from the lower Toarcian ‘Green Series’ are usually contained in syn genetically and early diagenetic carbonate concretions that occur interbedded within the clay. Based on the presence of a rich but taxonomically impoverished ammonite fauna and the scarcity of typical stenohaline invertebrates, marine-brackish water conditions have been inferred for the time of deposition of the ‘Green Series’ (Ernst, 1991; Ansorge, 2003, 2007). Reduced salinity conditions also are confirmed by occurrences of conchostracans (Ansorge, 2003; S.S., pers. observ.). The fauna mainly comprises actinopterygians (e.g., Jaekel, 1929; Malzahn, 1963; Thies, 1989; Ansorge, 2007; Ansorge and Obist, 2015; Konwert and Stumpf, 2017; Maxwell and Stumpf, 2017), followed by marine reptiles (Maisch and Ansorge, 2004; Stumpf, 2016) and rare chondrichthyans (Ansorge, 2007). These faunal elements occur alongside an extraordinarily rich terrestrial entomofauna (Ansorge, 1996, 2003), indicating the presence of suitable environments nearby. The ‘Green Series’ of Grimmen has also yielded abundant plant and wood remains, as well as the first Early Jurassic spider and basal sauropod dinosaur remains (Ernst, 1967; Selden and Dunlop, 2014; Stumpf et al., 2015) that were washed into the transcontinental shelf sea, suggesting a nearshore depositional environment, as proposed by Ernst (1967, 1991) and Ansorge (2003).

Significantly, the boundary between the tenuis-costatum and falciferum zones coincides with the height of the Toarcian Oceanic Anoxic Event (T-OAE), which is considered to be one of the most dramatic environmental disruptions that took place during the Mesozoic and massively impacted marine biota (e.g., Little and Benton, 1995; Caswell et al., 2009; Dera et al., 2010; Caswell and Cee, 2014). The ‘Green Series’ therefore documents a marine ecosystem immediately following the onset of the T-OAE.

MATERIALS AND METHODS

The pycnodontiform prearticular jaw bone, GG 437, described herein was initially found embedded in a carbonate concretion recovered from the lower Toarcian ‘Green Series’ clay deposits by one of us (J.A.) in 2005, who subsequently extracted the specimen from the surrounding matrix using diluted acetic acid. The specimen is preserved in three dimensions, and it is coated with pyrite in many places, lending it a somewhat gilded appearance. The second specimen, MV 202615, an isolated pycnodontiform tooth crown, was recovered by private collectors, Bernd Röber and Hannes Löser, from a temporary upper Pliensbachian bioclastic-rich coarse-grained sand body accessible during the late years of active clay mining at the Grimmen site, which started in 1959–1960 and ended in 1995. The exact year of discovery is unknown.

Digital photographs were obtained using a digital compact camera (Nikon Coolpix 4500) and digital microscopes (Zeiss AxioCam HR3 housed at the GG; Keyence VHX-100D housed at the Department of Palaeontology, University of Vienna). For descriptive proposes, various measurements were taken from GG 437, and statistical parameters were calculated using PAST 3.12 (Hammer et al., 2001). In addition, GG 437 was scanned with a desktop micro- computed tomography (micro-CT) device (Bruker/Skyscan 1173 housed at the Department of Palaeontology, University of Vienna). With an image pixel size of 7.13 μm and an X-ray beam set at 50 kV, 160 μA, the average of three frames were taken under the rotation step of 2°.

Following the description of the new taxon, we provide a review of the Early and Middle Jurassic fossil record of pycnodontiforms and finally compare the standing diversity with that of the Late Triassic.

Terminology—The morphological terminology used in the text follows that of Noursall (1996b, 1999). Consequently, we use the term ‘coronoid process’ here, although this structure cannot be considered homologous to the coronoid process in non-pycnodontiform neopterygians, where it is formed by the dentary, the surangular, and/or the angular.
**SYSTEMATIC PALEONTOLOGY**

OSTEICHTHYES Huxley, 1880

ACTINOPTERYGII Cope, 1887

NEOPTERYGII Regan, 1923

PYCNODONTIFORMES Berg, 1937

**GRIINMENODON, gen. nov.**

Type Species—*Grimmenodon aureum*, sp. nov.

**Description**—Pycnodontiform fish showing the following unique combination of morphological characters: Prearticular with rather short and narrow symphysis; coronoid process rather low in dorsoventral directions; tooth plate forming a prominent posterior process; teeth oval to subcircular in occlusal outline, closely arranged in five well-defined longitudinal rows without intercalating teeth; main row flanked medially by one tooth row and laterally by three tooth rows; teeth of medial row obliquely oriented, tooth crowns with a single wrinkled wall surrounding a shallow apical furrow; teeth of main row well-defined and elevated, exhibiting a shallow and transversally directed apical furrow surrounded by a broad wrinkled wall and additional tubercles along the anterior margins; average width/length ratio of main teeth 1.58; first lateral row short and restricted to the anterior half of the tooth plate; second lateral row occupies two-thirds of the tooth plate length; teeth of the first and second lateral rows ornamented by coarse, irregularly arranged tubercles that surround a rounded and deep central apical indent; teeth of the third lateral row with shallow and transversally directed apical indent bordered by an elevated and regularly tuberculated wall.

**Etymology**—The name is derived from the type locality, Grimmen, and the Greek noun *odonti* (όδοντς), meaning tooth.

**GRIINMENODON AUREUM, sp. nov.**

(Figs. 2, 3)

Holotype—GG 437, left prearticular bone with dentition.

Locality and Horizon—Abandoned open-cast clay pit of Grimmen (Mecklenburg-Western Pomerania, Germany); *Harpoceras exaratum* subzone (*Harpoceras falciferum* zone, lower Toarcian, Early Jurassic) (see Ansorge, 2007).

Diagnosis—As for genus (by monotypy).

Etymology—From Latin, golden, and refers to the somewhat golden appearance of the teeth caused by spatial pyrite coatings.

**DESCRIPTION**

*Grimmenodon aureum*, gen. et sp. nov., is represented by an almost complete left prearticular with preserved teeth; only the anterior-most portion is missing. The prearticular measures 10.67 mm in total length and 8.92 mm in width (maximum distance measured between the coronoid process and the medial border). The symphysis is rather narrow and extends posteriorly as far as the middle of the tooth plate, exhibiting a slightly rugose surface texture, probably for the attachment of interconnective tissue (see Kriwet, 2004) (Fig. 2A). More posteriorly, the symphysis continues into a faint bony wall that demarcates part of the posteromedial margin of the bone. The coronoid process is rather low in dorsoventral height, with a slightly convex dorsal margin that meets the posterior margin at a curved angle (Fig. 2B). The coronoid process exhibits weakly developed ridges oriented parallel to the longitudinal axis of the tooth plate, probably for the insertion of part of the musculus adductor mandibulae (see Kriwet, 2001c). The base of the coronoid process extends posterolaterally beyond the tooth plate to form an elevated and anteroposteriorly elongated ridge in ventral view (Fig. 2A, C), which is consistent with Nursall’s (1996b) ‘coronoid ridge.’ Posteriorly, the prearticular forms a distinct process, which is slightly incurved medially.

The prearticular dentition consists of molariform teeth closely arranged in five longitudinal rows without intercalating teeth (Fig. 2A). The teeth are strongly ornamented in occlusal view, lacking any signs of abrasion. The main row, as preserved, is elevated and comprises nine transversally elongated teeth decreasing in size anteriorly. They form a somewhat curved line in occlusal view. The spaces between adjacent teeth slightly decrease anteriorly. The main teeth are larger than any of those positioned in the medial or the lateral tooth rows, with an average width/length ratio of 1.58 (see Table 1). They are oval in occlusal outline and exhibit a transversally wide apical furrow that follows the outer contour of the crown. A broad and more or less regularly wrinkled wall surrounds the apical furrow. The radiating ridges on the surrounding wall are more strongly developed along the anterior margin, and occasionally irregularly arranged tubercles also are present along the anterior margin (Fig. 2A, D). The posterior-most tooth preserved in the main row is less elevated than the other ones aligned in the corresponding row, and its crown is partially enclosed by cancellous bone formed by the tooth plate (Fig. 2A, D, E).

The main tooth row is flanked medially by one and laterally by three tooth rows. The medial row, as preserved, includes three oval and obliquely positioned teeth; the intermediate one is incomplete, lacking its crown. Medial teeth are arranged alternating with the teeth of the main row, appearing almost inserted into the gaps between the main teeth. They exhibit an apical indent that is surrounded by a wrinkled wall. Posterior to the medial row, the prearticular forms a deep furrow, exposing cancellous bone. The furrow is mediadly demarcated by the bony lamella that extends posteriorly from the symphysis part of the posteromedial margin of the bone.

The first lateral row is restricted to the anterior portion of the dentition and includes at least five teeth (Fig. 2A). They are low (not as elevated as the main teeth) and have a suboval occlusal outline, with an average width/length ratio of 1.13. The three anterior-most teeth are arranged with their main axes perpendicular to the long axis of the prearticular bone, whereas those of the posterior ones are oriented parallel to its long axis. The tooth crowns display generally the same occlusal surface ornamentation, exhibiting a round apical indent that is surrounded by a broad and strongly irregularly tuberculated wall.

The second lateral row includes eight teeth and extends anteriorly as far as two-thirds of the tooth plate length (Fig. 2A). The teeth are also low compared with those of the main row and have an oval contour in occlusal view; the average width/length ratio is 1.21. The first three teeth are oriented with their main axes parallel to the long axis of the prearticular, unlike the remaining ones of the second lateral row, which are arranged perpendicular to the prearticular long axis. The teeth are ornamented by coarse and irregularly arranged tubercles that surround a round to suboval central apical indent. The two anterior-most teeth are slightly placed in the spaces between the teeth of the first lateral row.

The third lateral row consists of eight teeth, which display a transversally oval contour in occlusal view; at least two further teeth are missing due to breakage (Fig. 2A). The teeth are larger and more widely spaced, as compared with those arranged in the first and second lateral rows. Their average width/length ratio is 1.22, similar to that of teeth of the second lateral row. The occlusal surface, however, more closely resembles that of the main teeth, showing a more or less regularly wrinkled wall that surrounds a transversally wide apical furrow. The radiating ridges along this margin are formed by two to three small tubercles. The lateral edges...
of the teeth slightly overhang the dorsolateral margin of the prearticular (Fig. 2B).

The teeth are mounted on pedicles, which are clearly visible in lateral view, and numerous minute foramina are irregularly aligned along the dorsolateral surface of the prearticular (Fig. 2C). Internally, the tooth-bearing bone exhibits an irregularly spongy texture (Fig. 3), similar to the condition seen in a sectioned prearticular of Gyrodus cuvieri Agassiz, 1844, figured by Nursall (1996b:fig. 8; see also Kriwet, 2005:fig. 23). However, the micro-CT transverse slice shows spatial differences in the development of the internal spongy bone, in particular in the symphyseal region, where the irregularly arranged spongy bone is more strongly developed and even more densely packed, which is probably accompanied by enhanced jaw adductor forces (see Kriwet, 2001c, 2004). In addition, the coronoid process and the posteromedially extending bony wall show a slightly more regularly arranged spongy bone texture, giving a somewhat fibrolamellar appearance to it (Fig. 3E–H).

The minute foramina aligned along the dorsal margin of the lateral surface below the third lateral tooth row of

**Abbreviations:** aMxWT/MxLT, average of relative length proportions; LR1, first lateral tooth row; LR2, second lateral tooth row; LR3, third lateral tooth row; MDJ, medial tooth row; MR, main tooth row; MxLT(R), maximum length of teeth and variation of measurements (refers to the shortest length available) and variation of measurements; MxW(T), maximum width of teeth (refers to the greatest length available, regardless of tooth orientation) and variation of measurements (as indicated by ‘(R)’); NTM, number of complete teeth preserved in tooth row.

Compared to other pycnodontiforms, the Grimmenodon aureum shows a distinct pattern of tooth arrangement and development. The species exhibits a displaced molariform tooth crown showing an oval occlusal contour with a ring of widely spaced tubercles that ever, exhibits a displaced molariform tooth crown showing an oval occlusal contour with a ring of widely spaced tubercles that is distinctive of the genus. The pulp cavities of the teeth aligned in the main row are larger and deeper than those of the medial and lateral teeth (Fig. 3). The pulp cavities are free of bone tissue, and there is no indication of developing tooth germs or non-functional teeth inside the tooth-bearing bone adjacent to or below erupted teeth. Distinction between circumpolar dentine, pallial dentine, and acrodin cap (see Krüwit, 2005) was not possible based on the micro-CT scan.

**COMPARISON AND DISCUSSION**

So far, only a single Early Jurassic pycnodontiform species, *Eomesodon liassicus* (Egerton, 1855) from the Sinemurian of Barrow-on-Soar, Leicestershire, England (Egerton, 1855; Gardiner, 1960), has been described. The material consists of three poorly preserved articulated specimens. Unfortunately, the prearticular dentition of *Eomesodon liassicus* is insufficiently known to determine the total number of tooth rows, thus preventing detailed comparisons with *Grimmenodon aureum*, gen. et sp. nov. The holotype specimen of *Eomesodon liassicus*, however, exhibits a displaced molariform tooth crown showing an oval occlusal contour with a ring of widely spaced tubercles that encloses a shallow apical furrow (Egerton 1855:pl. 10, fig. 4), which is characteristic for teeth of *Eomesodon* (J.K., pers. observ.). This readily differentiates dentitions and teeth of *Eomesodon* from *Grimmenodon aureum*, gen. et sp. nov. Additional material referred to *Eomesodon liassicus* was reported from the Hettangian of France and Belgium, incorporating teeth and dentitions (Saint-Seine, 1949; Delsate et al., 2002). Duffin (2010:pl. 78, fig. 5) pictured a polished coprolite from the lower Early Jurassic of the Dorset Coast, England, containing inclu-
sions of bony remains, including an incomplete, coronally broached pycnodontiform dentition that displays two rows of widely spaced and regularly rounded teeth (see also Buckland, 1829:pl. 30, figs. 2, 3a), which were previously interpreted by Buckland (1829) as suckers of a squid.

Sauvage (1878) introduced the species *Gyrodus fabrei* based on a single left prearticular recovered from Early Jurassic (probably Toarcian; Priem, 1908) strata near Nancy, Meurthe-et-Moselle, France. This taxon is, however, considered invalid by Krüwit (2001a), who identified it as *Eomesodon* sp. More recently, Pászti (2004) reported pycnodontiform material from the Toarcian Úrúk manganese carbonate deposits (Úrúk Manganese Formation) of Hungary. This work, however, must be regarded with the utmost caution, because the fossil specimens pictured by Pászti (2004:figs. 1, 2) are not actually pycnodontiforms. Moreover, it is to be noted that Pászti’s (2004:fig. 3) line drawing of “*Eomesodon sp.*” is adapted from that of Stemmatodus rhombus (Agassiz, 1844) provided by Poyato-Ariza and Wenz (2002:fig. 12).

The oldest Middle Jurassic pycnodontiform record is represented by a single partially preserved skeleton recovered from the Bajocian Oolite Series of Scotland described as *Gyrodus goweri* by Grey-Egerton (1869). This species is considered as invalid by Krüweit and Schmitz (2005), because the material does not provide sufficient morphological traits to unambiguously assign it to a species and subsequently was referred to as *Gyrodus sp.* Unlike in *Grimmenodon aureum*, gen. et sp. nov., teeth of *Gyrodus*, when unburnt, exhibit two crenulated apical rings with a central tubercle, and a medial or lateral apex on the inner ring (Thiès, 1985; Krüweit, 2000; Krüweit and Schmitz, 2005). Moreover, *Gyrodus* can be clearly differentiated from the new taxon based on the presence of four prearticular teeth (Poyato-Ariza and Wenz, 2002).

A rather diverse pycnodontiform ichthyofauna was reported from the Bathonian Great Oolite Group of England, incorporating isolated dentitions of *Eomesodon rugulosus* (Agassiz, 1844), *E. trigonus* (Buckland, 1837), *Macromesodon bucklandi* (Agas-
siz, 1844), *M. discoides* (Agassiz, 1844), *M. oblongus* (Agassiz, 1844), *M. tenuidens* (Woodward, 1890), and *Proscinutes biseriatus* (Agassiz, 1844) (Woodward, 1890, 1892, 1895). In addition, isolated dentitions attributed to different species of *Macromesodon* also were reported from the Bathonian of France, including *M. bathonicus* (Sauvage, 1880b), *M. boloniensis* (Sauvage, 1867), *M. discoides*, *M. gervaisi* (Sauvage, 1867), and *M. radiatus* (Agassiz, 1844) (Sauvage, 1867, 1880a, 1880b). Furthermore, pycnodontiform teeth of Bathonian age were described from France (Kriwet et al., 1997) and Italy (Bassani, 1885). The taxonomy of Bathonian pycnodontiforms, however, is very poorly understood. For instance, as widely accepted, the genus *Macromesodon* comprises an unnatural grouping of unrelated taxa (Kriwet, 2001a; Poyato-Ariza and Wenz, 2002, 2004). Subsequently, Poyato-Ariza and Wenz (2004) restricted *Macromesodon* to the Late Jurassic species *M. macropreus* (Agassiz, 1834), *M. gibbosus* (Wagner, 1851), and *M. surgenso* (Poyato-Ariza and Wenz, 2002) and erected the genus *Turbaemosodon* for some Late Jurassic pycnodontiforms previously included in *Macromesodon*. According to the generic diagnoses provided by these authors, the prearticular dentition of both *Macromesodon* and *Turbaemosodon* comprises three tooth rows, a feature readily separating these taxa from *Grimmenodon aureum*, gen. et sp. nov., in which the prearticular teeth are arranged in five rows. Conversely, *Proscinutes biseriatus*, which is known from a single left prearticular recovered from the Great Oolite of Oxfordshire, has four rows (Woodward, 1890:pl. 3, fig. 28).

The prearticular dentitions of nominal species assigned to *Eomesodon* and *Macromesodon* are considered to be similar by Woodward (1895), exhibiting one main row, one or two medial rows, and at least three lateral rows. Among the Bathonian species, the arrangement of prearticular teeth in five longitudinal rows is present in *Eomesodon rugulosus* and *Macromesodon bucklandi* (Woodward, 1890, 1895). Remains referred to these species occur most frequently in strata of the English Great Oolite Group (see Woodward, 1895). Six tooth rows are present in *Macromesodon tenuidens* (Woodward, 1890:pl. 3, fig. 23), a rare taxon known from a single right prearticular recovered from the middle Biblical Formation of
FIGURE 3. Grimmenodon aureum, gen. et sp. nov., GG 437, holotype, from the lower Toarcian of Grimmen, Mecklenburg-Western Pomerania, Germany. A–H. digitally reconstructed 2D and 3D transverse slices from micro-CT scan (the positions of the transverse section planes are shown in Fig. 2A; B, D, F, and H are presented as red-cyan stereo anaglyphs, use red-cyan glasses to view). Dashed lines indicate boundary of pulp cavities. Abbreviations: cor.pr, coronoid process; for, foramen; p.cav, pulp cavity; sp.b, spongy bone; sym, symphysis; tr, tooth root.
Stonesfield, Oxfordshire, England, as well as in *Macromesodon gervaisi* (Sauvage, 1867:pl. 2, fig. 4; 1880a:pl. 14, fig. 2) and *Macromesodon boloniensis* (Sauvage, 1867:pl. 2, figs. 2, 5) from the Bathonian of Boulogne-sur-Mer, Pas-de-Calais, France. These taxa vary in the arrangement and occlusal contour of the teeth. *Macromesodon bathonicus*, which is known from a single partially preserved left prearticular described by Sauvage (1880b:pl. 19, fig. 1), is too incomplete to ascertain whether it represents a distinct species. *Macromesodon oblongus* and *M. discoides* are only known by their vomerine dentitions. Their teeth, however, markedly differ from those of *Grimmenodon aureum*, gen. et sp. nov.: e.g., regularly rounded and irregularly arranged in *M. discoides* (Woodward, 1890:pl. 3, fig. 32), and oval but oriented with their main axes parallel to the long axis of the corresponding bone in *M. oblongus* (Agassiz, 1844:pl. 19, fig. 10).

Pycnodontiform remains of Callovian age have been rarely reported in the literature. For instance, Kriwet (2008) figured an isolated left prearticular of an indeterminant species of *Athrodon* Sauvage, 1880b, recovered from the Callovian of Falaise des Vaches Noires near Dives-sur-Mer, Calvados, France. Unlike in *Grimmenodon*, gen. et sp. nov., the prearticular dentition of *Athrodon* includes more than five rows of circular teeth, which are irregularly arranged and more widely spaced, with the main row being usually less well-differentiated.

The pycnodontiform *Mesturus leedsii* Woodward, 1895, from the Callovian Peterborough Member (formerly named the Lower Oxford Clay) of Peterborough, Cambridgeshire, England, is known from three-dimensional preserved cranial material (Woodward, 1895, 1896). In addition, Wenz (1968) described a three-dimensionally preserved endocranium from the Callovian of Calvados, France, which she tentatively assigned to *Mesturus* sp. The species *Mesturus leedsii* exhibits a total number of five prearticular teeth rows, including three regular and two irregularly arranged rows of low and small teeth aligned between the main and the lateral one (Woodward, 1896:pl. 2, fig. 3), a character combination that easily distinguishes it from the new taxon described herein.

Thus, it is evident that the prearticular dentition of *Grimmenodon aureum*, gen. et sp. nov., is distinct from all other known pycnodontiforms in possessing an inconspicious, anteriorly restricted first lateral row of small subcircular teeth, and a conspicuous large variability of occlusal tooth ornamentation.

**Size, Ontogeny, and Tooth Development**

The prearticular of *Grimmenodon aureum*, gen. et sp. nov., is of comparatively small size, suggesting a hypothetical small standard length of the fish of about 7–10 cm at the time of death, when compared with *Gyrodon* and *Proscinetes* (Licht, 2009; Licht et al., 2015). The strong occlusal sculpturing of the teeth is suggestive of an immature ontogenetic stage, because the vomerine and prearticular dentitions of pycnodontiforms usually become worn during ontogeny, resulting in smooth tooth crowns during individual growth at least in the anterior portions of the dentition (see Kriwet, 2005). Tooth development in pycnodontiform fishes has been discussed in the literature for many years. For instance, Nursall (1996b) proposed that pycnodontiforms formed a single generation of molariform teeth without replacement of individual teeth. Woodward (1893, 1895) and Thurmond (1974) suggested that the number of teeth was increased by the addition of larger ones formed posterior to functional teeth simultaneously to caudally directed prearticular and vomer growth, a view supplemented by Longbottom (1984), who, however, proposed both an anterior and a posterior additional tooth development, in which the anterior teeth were replaced by small, irregularly arranged teeth. More recently, Poyato-Ariza and Wenz (2005) described a non-functional tooth preserved in situ within the posterior part of the prearticular of their new taxon *Akromystax tilmachiton* from the Late Cretaceous of Lebanon. This tooth was found at an angle of about 90° to the occlusal surface of the corresponding bone, which might indicate a similar mode of tooth development as described in the ginglymodian fish *Lepidotes* (Peyer, 1954). Based on the observations obtained from *Akromystax tilmachiton*, Poyato-Ariza and Wenz (2005) suggested that a formation of posterior additional, non-successional prearticular teeth was possible in pycnodontiform fishes, probably in order to compensate for simultaneous tooth abrasion, which generally first affected anterior teeth and later those positioned in the posterior part of the tooth plate. Similar teeth positioned in occlusally open sockets posterior to functional teeth are commonly present in pycnodontiforms (e.g., Kriwet, 2005:fig. 23). The micro-CT–generated transverse slices of *Grimmenodon aureum*, gen. et sp. nov., undoubtedly reveal the absence of neither non-functional teeth nor developing tooth germs preserved within the prearticular tooth plate. Otherwise, the posterior-most tooth preserved in the main prearticular tooth row in *Grimmenodon aureum*, gen. et sp. nov., is less elevated and still partially covered by spongy bone, which might suggest that this tooth was not yet fully functional and still developing at the time of death, thus giving further support to the interpretation of additional non-successional tooth development initiated inside the posterior part of the prearticular tooth plate. Assuming this interpretation to be correct, it is conceivable that at this stage of development, the tooth was growing in height while the spongy bone covering of the tooth crown was resorbed, similar to the condition seen in the extant durophagous teleost *Anarchichas lupus* Linnaeus, 1758 (Bemis and Bemis, 2015). During further development, the tooth crown could grow in width and length to occupy the available space between adjacent teeth. Given the limited available space, this stage of development was probably occasionally accompanied by a reorientation of the major tooth axes, as suggested by some teeth in the first and second lateral rows.

**Pycnodontiformes**, gen. et sp. indet.

(Fig. 4)

**Referred Material**—MV 202615, an isolated tooth crown.

**Locality and Horizon**—Abandoned open-cast clay pit of Grimen (Mecklenburg-Western Pomerania, Germany); *Pleurocercus ayyrenum* subzone (*Pleurocercus spiniatum* zone, upper Greensbachian, Early Jurassic) (see Ernst, 1991).

**Description**—MV 202615 represents an isolated tooth crown. The specimen is low and oval in occlusal view, with the minor axis being 1.48 times that of the major axis. The occlusal surface shows no apical indentation or ornamentation. There are no signs of breakage at the base of the tooth crown and the lower margin is continuous.

**Comparison**—The smooth, low oval morphology of MV 202615 is characteristic of pycnodontiform molariform teeth, although this kind of tooth crown morphology also occurs in some ginglymodian fishes (e.g., Jain and Robinson, 1963:pl. 1, fig. 7). However, teeth of ginglymodians usually bear a distinct sheath of collar ganoit that embraces the base of the tooth crown and upper part of the associated tooth neck (e.g., Olsen and McCune, 1991). The collar ganoit in molariform teeth of pycnodontiforms, conversely, is strongly reduced (Kriwet, 2005), and the teeth usually exhibit a distinct constriction at the crown-root junction. Consequently, pycnodontiform tooth crowns typically remain isolated and devoid of an associated tooth neck when broken off, unlike the condition seen in ginglymodians, where teeth mostly display at least remnants of the tooth neck and base (e.g., Mudroch and Thies, 1996; Cuny et al., 2010; Pouech et al., 2015). This provides strong support that MV 202615 can be assigned to Pycnodontiformes. The absence of ornamentation in
MV 202615 most likely is due to abrasion and prevents more detailed comparisons with other known pycnodontiforms but seems to differentiate it from the new taxon described above. Consequently, MV 202615 is identified here as Pycnodontiformes gen. et sp. indet.

**Paleobiogeographic and Ecological Implications**

The two fossil specimens described herein represent the first reliable records of pycnodontiform fishes from the late Early Jurassic, complementing previous finds of early representatives of this distinctive group of basal neopterygians, which remain particularly scarce, especially in comparison with the rich and diversified pycnodontiform faunas from the Late Jurassic and Late Cretaceous (Kriwet, 2001a, 2001b; Poyato-Ariza and Martin-Abad, 2013). The material constitutes the northeasternmost records of pycnodontiform fishes from Europe known so far, confirming their presence before and immediately following the onset of the T-OAE in marginal marine ecosystems of the NGB south of the Fennoscandian Shield. However, it has to be mentioned that the fossil specimens also could be allochthonous; therefore, these forms might have inhabited more suitable areas during that time, such as the nearshore lagoonal depositional environments referred to the Baga Formation of Bornholm, Denmark (Koppelhus and Nielsen, 1994). The almost complete preservation and the lack of substantial signs of erosion seen in the prearticular of *Grimmenodon aureum*, gen. et sp. nov., at least, argue against an extensive postmortem transport and reworking, providing some support for the interpretation that the new taxon is autochthonous, but more material is needed to test whether *Grimmenodon aureum*, gen. et sp. nov., formed an obligatory part of the marine vertebrate biota obtained from the lower Toarcian ‘Green Series’. Conversely, the herein described indeterminate molariform pycnodontiform tooth crown recovered from the sandy, shallow-marine upper Pliensbachian co-occurred with abundant chondrichthyan remains that have suffered massively from postmortem damage in many places (S.S., pers. observ.), suggesting reworking and redistribution generated by current activities.

The presence of a pycnodontiform fish in the lower Toarcian ‘Green Series’ vertebrate biota separates it from all other time-equivalent marine vertebrate communities reported from different localities all over Europe (Wenz, 1968; Hauff and Hauff, 1981; Urlich et al., 1994; Delsate, 1999; Vincent et al., 2013; Hauff et al., 2014; Williams et al., 2015). This disparity, combined with the interpretation that these localities largely document more open-marine depositional environments, is in good accordance with the interpretation that pycnodontiforms were predominantly linked to marginal marine environments, as inferred from paleobiogeographical and ecomorphological evidence (Nursall, 1996a; Kriwet, 2001a, 2001b; Kriwet and Schmitz, 2005; Poyato-Ariza, 2005; Martin-Abad and Poyato-Ariza, 2013). This specific distribution pattern probably can be related to diverse environmental and/or biological constraints (Poyato-Ariza and Martin-Abad, 2013), such as swimming capabilities and the availability of preferred food resources, but also to collecting biases.

With regard to the robust molariform dentition seen in the prearticular of *Grimmenodon aureum*, gen. et sp. nov., this taxon appears to have been well adapted to durophagy, inferring a predominant diet of especially hard food items. Taking into consideration the fossil assemblage recovered from the lower Toarcian ‘Green Series’, potential food resources for durophagous fish include ammonites, the supposed facultative pseudoplanktonic inoceramid bivalve *Pseudomytoloides dubius* (Sowerby, 1829), and the holoplanktonic coelodiscid gastropod *Coelodiscus minutes* (Schübler in Zieten, 1830–1833), as well as crustaceans. In this context, it is interesting to note that the ‘Green Series’ also yielded remains of the dapediform neopterygian fish *Dapedium* Leach, 1822 (Oertel, 1921; S.S., pers. observ.), which is interpreted as well adapted to durophagy, as seen in the functional morphology of the jaw and tooth morphology (Smithwick, 2015), but see Thies and Hauff (2011), who consider *Dapedium* to be a generalist feeder.

The Early Jurassic neopterygians *Lepidotes Agassiz, 1832*, and *Tetragonolepis* Bronn, 1830, which are considered to be at least facultative durophagous based on their dentitions (e.g., Quenstedt, 1847; Woodward, 1897; Thies, 1991), also are known from the ‘Green Series’ (Jaekel, 1929; Malzahn, 1963; Thies, 1989; Ansorge, 2007; Zessin and Krempien, 2010). Although dental evidence is suggestive of ecological niche overlap, the disparity in morphological adaptations in *Dapedium*, *Tetragonolepis*, and *Lepidotes* is likely to have played a role in the foraging mode and, consequently, in the segregation of available food resources. Notwithstanding the fact that the body and fin forms of
Grimmenodon aureum, gen. et sp. nov., remain unknown, it is intriguing to note that the deep-bodied and laterally flattened dapediidiform fishes Dapedium and Tetragonolepis fall within the general morphospace occupation area of pycnodontiforms (Fig. 5), which indicates taxa well adapted to maneuvering as well as generalist swimming forms (see Poyato-Ariza, 2005). Accordingly, based on indirect evidence, it seems reasonable to conclude that Grimmenodon aureum, gen. et sp. nov., was in competition with taxa such as Dapedium and Tetragonolepis and may have used alternative strategies in order to partition food resources and avoid direct competition.

LATE TRIASSIC–EARLY JURASSIC DIVERSITY PATTERNS

The Triassic-Jurassic mass extinction event is one of the ‘big five’ Phanerozoic extinction events, with a loss of almost 50% of marine genera and significant terrestrial faunal and floral turnover (e.g., Raup and Sepkoski, 1982; Youbi et al., 2014). The early history of pycnodontiform fishes still is poorly understood, and their diversity patterns across this important biotic event have not been established so far, because many species are in need of revision or must be considered dubious. This is because pycnodontiforms from the Early and Middle Jurassic are rare and mainly represented by isolated vomerine and prearticular teeth, which are difficult to identify or included in phylogenetic analyses for establishing their diversity after the Triassic-Jurassic mass extinction seems to have crossed this boundary and is present with a single species, E. iassicus, in the Hettangian-Sinemurian (Saint-Seine, 1949; Gardiner, 1960; Delsate et al., 2002). The apparent taxonomic diversity reduction in the Early Jurassic supports the supposition that pycnodontiform fishes were affected by the Triassic-Jurassic mass extinction event coming from few stratigraphic levels. Obviously, the pycnodontiforms Gibbodon and Brembodus vanished before or in conjunction with the Triassic-Jurassic mass extinction event. Only the genus Eomesodon can be considered to have crossed this boundary and is present with a single species, E. iassicus, in the Hettangian-Sinemurian (Saint-Seine, 1949; Gardiner, 1960; Delsate et al., 2002). The apparent taxonomic diversity reduction in the Early Jurassic supports the supposition that pycnodontiform fishes were affected by the Triassic-Jurassic mass extinction event.

CONCLUSIONS

The new Early Jurassic pycnodontiform material shows that their diversity after the Triassic-Jurassic mass extinction seems to have crossed this boundary and is present with a single species, E. iassicus, in the Hettangian-Sinemurian (Saint-Seine, 1949; Gardiner, 1960; Delsate et al., 2002). The apparent taxonomic diversity reduction in the Early Jurassic supports the supposition that pycnodontiform fishes were affected by the Triassic-Jurassic mass extinction event coming from few stratigraphic levels. Obviously, the pycnodontiforms Gibbodon and Brembodus vanished before or in conjunction with the Triassic-Jurassic mass extinction event. Only the genus Eomesodon can be considered to have crossed this boundary and is present with a single species, E. iassicus, in the Hettangian-Sinemurian (Saint-Seine, 1949; Gardiner, 1960; Delsate et al., 2002). The apparent taxonomic diversity reduction in the Early Jurassic supports the supposition that pycnodontiform fishes were affected by the Triassic-Jurassic mass extinction event.
modern morphological, taxonomic descriptions and revisions of known material, as well as additional material, are necessary to establish statistically supported diversification and diversity patterns in the future.

ACKNOWLEDGMENTS
S.S. is indebted to I. Hinz-Schallreuter (GG) for her continued help and support. K. Obst (MV) is acknowledged for providing access to the collection in his care. S. Meng and M. Konwert (both GG), G. Kainer (Department of Palaeontology, University of Vienna), M. Hörning (Zoological Institute and Museum, University of Greifswald), and M. Ebert (Jura-Museum Eichstätt) are thanked for valuable suggestions and discussions. A. López-Arbarello (Bayerische Staatssammlung für Paläontologie und Geologie, Munich) and G. Arratia (University of Kansas) provided comments that improved the manuscript. S.S. was financially supported by a Ph.D. scholarship of Mecklenburg-Western Pomerania. Financial support for this project also was provided by the Austrian Science Fund (FWF: P29796-B29) to J.K.
