The ability of proteins to associate with genomic DNA in the context of chromatin is critical for many nuclear processes including transcription, replication, recombination, and DNA repair. Chromatin immunoprecipitation (ChIP) is a practical and useful technique for characterizing protein / DNA association *in vivo*. The procedure generally includes six steps: (1) crosslinking the protein to the DNA; (2) isolating the chromatin; (3) chromatin fragmentation; (4) immunoprecipitation with antibodies against the protein of interest; (5) DNA recovery; and (6) PCR identification of factor associated DNA sequences. In this protocol, we describe guidelines, experimental setup, and conditions for ChIP in intact Arabidopsis tissues. This protocol has been used to study association of histone modifications, of chromatin remodeling ATPases, as well as of sequence-specific transcription factors with the genomic DNA in various *Arabidopsis thaliana* tissues. The protocol described focuses on ChIP-qPCR, but can readily be adapted for use in ChIP-chip or ChIP-seq experiments. The entire procedure can be completed within 3 days.

I. INTRODUCTION

In eukaryotes, DNA is packaged into chromatin. Chromatin is composed of DNA, proteins, and RNA and is the substrate for nuclear processes such as transcription, replication, recombination and repair (Rando and Ahmad, 2007; Margueron and Reinberg 2010). Many proteins directly or indirectly contact genomic DNA in the context of chromatin. For example, gene expression is modulated by proteins with diverse functions such as structural proteins that make up the nucleosome, histone modification readers, enzymes modulating chromatin structure, sequence specific binding proteins and their cofactors, or the general transcriptional machinery (Li et al., 2007; Clapier and Cairns, 2009; Alabert and Groth 2012; Spitz and Furlong 2012).

To understand the contribution of these factors to the regulation of key nuclear processes, techniques that probe their association with the genomic DNA are of central importance. Several *in vitro* techniques, such as electrophoretic mobility shift assays or yeast one-hybrid assays are commonly used to determine DNA-protein interactions. However, *in vitro* interactions could be forced and may not reflect the situation in cells. Chromatin immunoprecipitation (ChIP) represents a valuable alternative for probing such interactions *in vivo* (in isolated cells, tissues or entire seedlings) under physiological conditions and to estimate the density of protein at specific sites (Kuo and Allis, 1999). In addition, this

technique allows investigation of change in protein association with the DNA in response to cue and the temporal relationship of this change relative to changes in transcription.

The first ChIP protocol was developed by Gilmour and Lis (1984, 1985, 1986) to monitor RNA polymerase II/ DNA association in *Escherichia coli* and *Drosophila*. The use of formaldehyde for fixation in ChIP was pioneered by Solomon et al (1988). After publication of this method, formaldehyde was commonly used in ChIP experiments for most organisms. A general ChIP assay consists of six steps: (1) Crosslinking the protein to the DNA, (2) Isolation of chromatin from a nuclear extract, (3) Fragmentation of chromatin, (4) Immunoprecipitation, (5) Recovery of DNA, and (6) PCR identification of associated DNA sequences, hybridization to tiling arrays, or high throughput sequencing (Figure 1). The complete protocol for ChIP-qPCR starting from plant harvest takes 3 days (Figure 2).

Because of anatomical differences between animal and plant cells, such as rigid cell walls, high levels of cellulose and lignin, and large vacuoles in plant cells, several modifications are needed to establish efficient ChIP protocols for plant systems. Vacuum infiltration is applied to allow the formaldehyde to penetrate into plant cells and nuclei. In addition, use of young plant tissues increases the yield of nuclei per gram fresh weight. Many variations of the ChIP protocol for plants have been published. For examples see: (Gendrel et al., 2002; Saleh et al., 2008; Kaufmann et al., 2010).

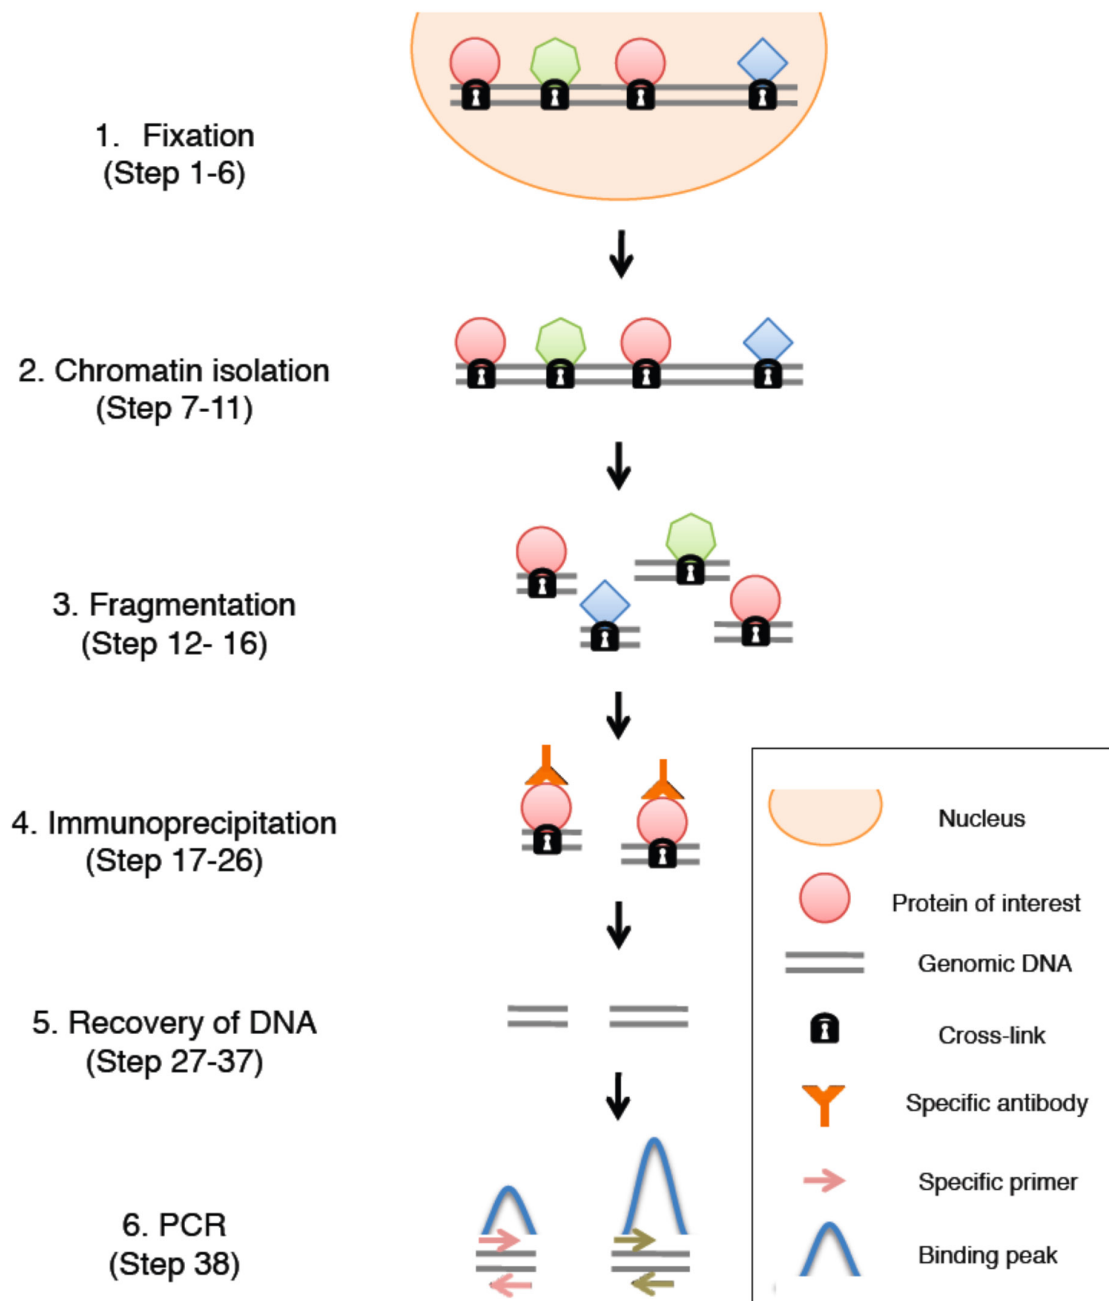

Figure 1. Outline of the ChIP procedure. After cross-linking with formaldehyde, the cells are lysed and the nuclei-containing fraction is isolated. After chromatin shearing, the samples are incubated with antibodies for immunoprecipitation. After crosslink reversal, PCR-ready DNA is collected. Binding of the protein of interest to genomic DNA is examined by real-time PCR.

Here, we provide guidelines and conditions for highly efficient and specific ChIP using Arabidopsis tissues. We have reduced the number of experimental steps required to shorten preparation time. We suggest that a well-controlled ChIP experiment requires two types of negative controls: a) a genetic control, b) a genomic control. For the former, we recommend use of null mutant plants, if gene-specific antibodies are employed (Wu et al., 2012), or use of a non-transformed parental line, if an epitope tagged protein is

used (Yamaguchi et al., 2013). These controls are more stringent than use of IgG antibody or no antibody, because the experimental and control samples are subjected to identical conditions. For the genomic control, a locus unlikely to be bound by the factor of interest should be tested for each experimental and control ChIP reaction. Even if no prior ChIP data is available for the factor of interest, suitable genomic controls can be chosen. For example, housekeeping genes can serve as genomic controls for both

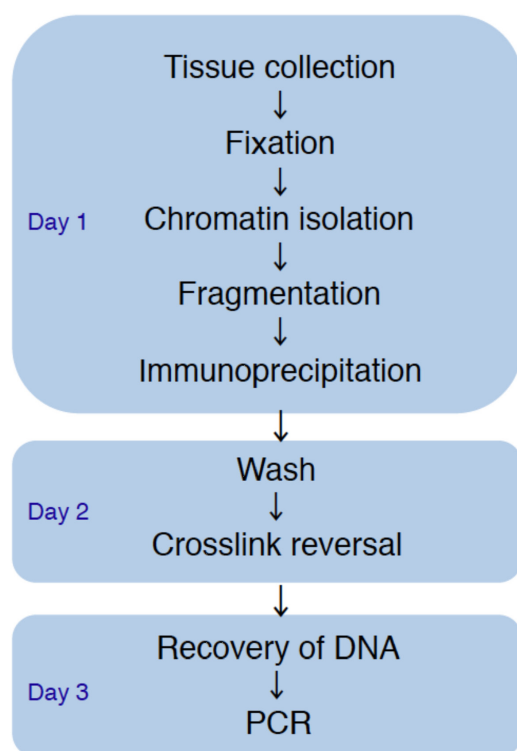

Figure 2. Flowchart for a typical ChIP experiment and sample processing.

Figure 3. Example of a ChIP assay. H3K27me3 ChIP was performed in the wild-type and in a PRC2 complex mutant (*clf-2*; genetic control). 10-day-old plants were grown on 1/2 MS medium in long-day condition. H3K27me3 antibody (5 μ L; AbCam) was used. ChIP DNA was amplified by real-time PCR using either a pair of primers to the second intron of a known PRC2 target gene, *AGAMOUS* intron 2 (*AGi2*; *AGi2*-FW: CGTTGTGATGTTACTCGGACA; *AGi2*-FW: CAACAACCCATTAAACACATTGG) or to the promoter of the *ACT1N2* (*ACT2*) housekeeping gene (Table 1, Wu et al., 2012). Mean \pm s.e.m of three technical replicates from one representative biological replicate are shown. At least 3 biological replicates were performed.

tissue-specific transcription factors (Yamaguchi et al., 2009; Yamaguchi et al., 2013) or repressive chromatin regulators such as Polycomb complex components (Table 1, Figure 3). For activating chromatin regulators, a silenced locus (such as a retrotransposon) is a good negative genomic control (Wu et al., 2012; Table 1). Including these controls in the final ChIP data figures will allow the reader to assess the relative strength of the experimental and control ChIP signals and hence the true ChIP enrichment (Figure 3; Yamaguchi et al., 2009; Wu et al., 2012; Yamaguchi et al., 2013).

To establish the ChIP procedure in the lab for the first time, we suggest performing a ChIP experiment in seedlings using antibodies to histone H3K27me3. Extensive genome-wide datasets are available that have employed this strategy (Zhang et al., 2007) and excellent positive and negative control loci are known (Figure 3). In addition, this modification is abundant in the nucleus and effective and specific commercial antibodies are available (For examples, see Table 2). Additional optimization might be needed if instruments differ from those described here. In addition, further optimization may be required if different types of tissues are sampled or for ChIP performed in different plant species.

II. MATERIALS

II-A. Reagents

Formaldehyde 37 % (Sigma, cat. no. F1635)
 Glycine (Fisher Scientific, cat. no. BP381-1)
 Disodium hydrogen phosphate (Sigma, cat. no. S0876)
 Sodium phosphate (Sigma, cat. no. S0751)
 Sodium chloride (Fisher Scientific, cat. no. BP358-212)
 Magnesium chloride (Sigma, cat. no. M3634)
 MOPS (Sigma, cat. no. M1254)
 Sucrose (Fisher Scientific, cat. no. BP220-1)
 Dextran T-40 (Sigma, cat. no. D1662)
 Ficoll 400 (Sigma, cat. no. F4375)
 β -Mercaptoethanol (Sigma, cat. no. M3148)
 Protease Inhibitor cocktail (Sigma, cat. no. P9599)
 Tris (Sigma, cat. no. 252859)
 EDTA (Fisher Scientific, cat. no. BP120)
 SDS (Sigma, cat. no. L3773)
 Triton X-100 (Sigma, cat. no. T9284)
 Lithium chloride (Sigma, cat. no. L9650)
 IGEPAL-CA630 (Sigma, cat. no. I3021)
 Deoxycholate (Sigma, cat. no. D6750)
 Dynal Protein A beads (Invitrogen, cat. no. 10002D) or Dynal Protein G beads (Invitrogen, cat. no. 10004D)
 Ethanol (Decon Labs cat. no. 2716)
 Power SYBR Green (Applied Biosystems cat. no. 4367659)
 Commercial antibodies (if epitope-tagged fusion proteins were expressed in plants). See Table 2 for suggestions.

II-B. Supplies and equipment

- Scintillation vials
- Miracloth (Calbiochem, cat. no. 475855)
- Sonicator
- Autoclave
- Magnetic stand (Promega, cat. no. Z5342)
- Tips
- 2 ml screw cap tubes (GeneMate, cat. no. C-3379-1)
- 1.5ml DNA LoBind tubes (eppendorf, cat. no. 022431021)
- Centrifuge
- Rotating mixer for 1.7 ml tubes
- Cold room
- Vortex mixer
- DNA purification kit (Qiagen cat. no. 28104)
- Filter (Corning Incorporated cat. no. 431117)
- Mortar and pestle
- Small funnel
- 65 degree incubator
- Real-time PCR machine

II-C. Buffers and solutions

- 10 × PBS** 1310 mM NaCl₂ 70 mM Na₂HPO₄, 30 mM NaH₂PO₄ (1 × PBS will be needed at RT and 4 degrees).
- Nuclei Extraction Buffer** 100 mM MOPS pH 7.6, 10 mM MgCl₂, 0.25 M Sucrose, 5 % Dextran T-40, 2.5 % Ficoll 400, 40 mM β-Mercaptoethanol (add fresh, do not include in stock), 1 × Protease Inhibitor (add fresh, do not include in stock). No need to autoclave or filter sterilize. Make sure that the MOPS buffer is fresh (no yellow coloration).
- Nuclei Lysis Buffer** 50 mM Tris-HCl pH 8.0, 10mM EDTA pH 8.0, 1 % SDS. (filter-sterilize; this buffer is also used for elution)
- ChIP Dilution Buffer without Triton** 16.7 mM Tris-HCl pH 8.0, 167 mM NaCl, 1.2 mM EDTA, 0.01 % SDS. (filter-sterilize)
- ChIP Dilution Buffer with Triton** 16.7 mM Tris-HCl pH 8.0, 167 mM NaCl, 1.2 mM EDTA, 1.1 % Triton X, 0.01 % SDS. (filter-sterilize)
- Low Salt Wash Buffer** 0.1 % SDS, 1 % Triton-X, 2mM EDTA, 20 mM Tris-HCl pH 8.1, 150 mM NaCl. (filter-sterilize)
- High Salt Wash Buffer** 0.1 % SDS, 1 % Triton-X, 2mM EDTA, 20 mM Tris-HCl pH 8.1, 500 mM NaCl. (filter-sterilize)
- 250 mM LiCl Wash Buffer** 0.25 M LiCl, 1% IGEPAL-CA630, 1 % deoxycholate, 1mM EDTA, 10 mM Tris-HCl pH 8.1. (filter-sterilize).

Table 1. Commonly used control loci and qPCR primer pairs

Gene name (AGI code)	Primer name	Sequence
EIF4A1 (At3g13920)	EIF4-FW	TGTTTTGCTTCGTTTCAAGGA
	EIF4-RV	GCATTTTCCCCGATTACAAC
ACT2 (At3g18780)	ACT2-FW	CGTTTCGCTTTCCTTAGTGTTAGCT
	ACT2-RV	AGCGAACGGATCTAGAGACTCACCTTG
TA3 retrotransposon	TA3-FW	CTGCGTGGAAGTCTGTCAAA
	TA3-RV	CTATGCCACAGGGCAGTTTT

Table 2. Commonly used antibodies and amounts used

Antibody	Company name	Catalog number	Amount
GFP antibody	Invitrogen	A6455	5 µL (protein amount not specified)
HA antibody	Roche	12C5	10 µL (10 mg)
FLAG antibody	Invitrogen	F3165	10 µL (8 mg)
H3K27me3	AbCam	Ab8580	5 µL (5 mg)
H3K4me3	AbCam	Ab6002	5 µL (5 mg)

III. PROCEDURE

III-A. Tissue collection and fixation

Duration: 1 h

- 1*. Harvest 300-600 mg of plant tissues into a 25 mL scintillation vial containing 10 mL of 1 × PBS solution. Preferably young and healthy tissue should be used.^{NOTES}
- 2*. Remove 1 × PBS with 10 mL pipette and replace with 10 mL room temperature 1 % formaldehyde solution in 1× PBS (270 µL 37 %) formaldehyde per 10 mL 1 × PBS) to cross-link tissue.^{NOTES}

CAUTION:

Formaldehyde is toxic; work in the fume hood.

- 3*. Vacuum infiltrate the tissue until it sinks (3 times for seedlings; 3-5 times for inflorescences), not exceeding 15 min total exposure time to formaldehyde. A typical seedling vacuum infiltration: pre-incubate in the fume hood: 4 min; first vacuum: 1.5 min (or stop when bubbles start to boil over); second or more vacuum: 1 min (bubbles should slow down by the end of vacuum time); post-incubate in hood: ~ 3 min).^{NOTES}
4. Remove formaldehyde in hood with 10 mL pipette and add 10 mL 0.125 M glycine solution (quenches the cross-linker). Vacuum once for ~1.5 min. The total glycine incubation time is 5 min.
5. Remove glycine in hood and rinse 2 times with 10 mL cold 1 × PBS solution on the lab bench (PBS should be cold to preserve cross-linking).
- 6*. Dry plant tissues briefly (blot on paper towel), weigh (should be 300-600 mg), and insert into 2 mL tubes. Freeze in liquid nitrogen.^{NOTES}

STOPPING POINT:

The tissue can be stored at -80 °C for up to 3 months.

NOTES AND TROUBLESHOOTING

- N1. *For samples that trap air between tissues (like the flower bearing stem of Arabidopsis plants called the inflorescence), we incubate the sample in PBS at room temperature for 2-3 h to ensure that most airspaces are occupied by liquid. This step is not necessary for leaves, stems, roots, or seedlings.*

300 mg of tissue is sufficient for one ChIP reaction using either entire seedlings or dissected inflorescences.

- N2. *The formaldehyde needs to be fresh. Prepare the PBS formaldehyde solution immediately prior to use.*

- N3. *Tissue needs to be submerged in the solution before starting the vacuum infiltration and throughout the infiltration.*

Vacuum infiltration allows the formaldehyde to penetrate into plant cells.

Tissues should sink to the bottom of the vials after the second vacuum release. If they still float, vacuum again.

- N6. *Do not freeze wet samples as ice will reduce the grinding efficiency.*

III-B. Nuclei isolation and shearing of chromatin **Duration: 2 h**

7. Add Protease Inhibitors (from 100 × stock) and β-Me (3.12 µL/mL) to Nuclei Extraction Buffer. Make 3.0 mL per sample.

CAUTION:

β-Me-containing solution; work in the fume hood.

8. Grind the samples to a fine powder using a mortar and pestle, keeping the tissue frozen throughout. After completion, add 2.5 mL nuclei extraction buffer with protease inhibitors and β-ME and keep grinding until the tissue is thawed.
9. Set up a small funnel over a 50 mL Falcon tube with two layers of Miracloth. Pass the filtrate through the Miracloth twice and transfer the filtrate to a fresh 2 mL tube. Be sure to squeeze the Miracloth after the second pass-through to extract all of the liquid (change gloves after each sample). Keep samples on ice until all samples have been processed.
10. Spin for 5 min at 10,000 g at 4 °C. Remove the supernatant and resuspend the pellet in 75 µL nuclei lysis buffer. This will require stirring with a pipette tip. Try to avoid foaming.
11. Leave sitting on ice for 30 min with occasional stirring. Subsequently bring up to a final volume of 700 µL with ChIP dilution buffer without Triton (add 625 µL). Transfer the solution to a new 1.5 mL tube.
- 12*. Sonicate five times for 10 seconds each (~ P3.2) with a Fisher Dismembrator or other sonicator (the size range of sheared DNA should be around 200-1000 bp; See Figure 4). Incubate the samples on ice for 50 sec between sonications to allow them to cool.^{NOTES}
13. Transfer the sonicated solution to a new 2 mL tube. A typical yield after sonication is 665 µL. Add 200 µL ChIP dilution buffer with Triton X-100 and 35 µL of 22 % Triton X-100 to attain 900 µL of sample with a 1.1 % Triton X-100 concentration.
14. Spin at full speed (13,200 rpm) for 5 min at 4 °C. Remove from the centrifuge immediately, and transfer the clean supernatant to a new 2 mL tube. Repeat this step one more time to remove as much of the pellet (debris) as possible.

NOTES AND TROUBLESHOOTING

- N12. *If samples get too hot, the proteins will be denatured. Try to avoid foaming. The formation of bubbles will reduce the sonication efficiency. Make sure the sonicator probe tip does not touch the side of the tube.*

Fragmentation efficiency determines the ChIP resolution. Sonication conditions must be determined empirically for

each tissue type and sonicator model; optimal average DNA fragment sizes are 200–1000 kb.

To test the sonication efficiency, incubate 100 μ L of supernatant from step 19 at 65 °C overnight (crosslink reversal) and purify it with DNA purification kit. Examine (30 μ L) of the resulting DNA with 6 \times DNA sample buffer on 1.5 % agarose gel. A DNA smear in the 200–1000 bp size range should be observed with a maximum peak around 500 bp in the sonicated samples (Figure 4).

III-C. Pre-clearing

Duration: 2 h

- 15*. For pre-clearing, add 50 μ L of magnetic protein A/G beads per tube. Incubate for 2 h at 4 °C with rotation. Place on magnetic stand. ^{NOTES}
16. Transfer cleared solution to a new 2 mL tube. Remove 2/100ths (18 μ L) as a 2% input sample and store it in a -20 °C freezer. Discard beads.

NOTES AND TROUBLESHOOTING

N15. Protein A and G have different specificity for different antibody classes and subtypes. For example, Protein A is more broad in its ability to bind human antibody types other than IgG, but it does not specifically bind IgG3 very well. On the other hand, Protein G binds all human IgG subtypes well. Protein G is also more versatile for binding to IgG subtypes from other species (Richman et al., 1982; Akerstrom et al., 1985).

Magnetic beads give high recovery and low background; they do not require centrifugation (will not pellet together with aggregates) and have less surface area to trap DNA or proteins non-specifically.

III-D. Immunoprecipitation

Duration: 16–20 h

including overnight incubation step

- 17*. Add a suitable amount of antibody per tube (see Table 2 for examples). Leave rotating overnight at 4 °C. ^{NOTES}
18. For immunoprecipitation capture DNA/protein complexes, add 50 μ L of protein A/G magnetic beads per tube. Incubate for 4 h at 4 °C with rotation.

NOTES AND TROUBLESHOOTING

N17. Whereas monoclonal antibodies recognize only a single epitope, polyclonal antibodies recognize multiple different epitopes. Use of polyclonal antibodies will reduce the probability that all specific epitopes are masked by cross-linking, so there is a better chance to get a positive result for IP. Also polyclonal antibodies usually give higher ChIP signals than a monoclonal antibody.

To determine the amount of antibody to use, start with a well-characterized antibody (H3K27me3). Too much antibody can

Figure 4. Fragmentation of chromatin by sonication. Lane 1: Size Marker; Lane 2: Aliquot (200 ng) of sonicated DNA from step 19.

lead to high background. Too little antibody will lead to low or no signal. The amount of antibody required per ChIP typically ranges from 1–10 μ g of antibody per 25 μ g of chromatin.

A key determinant of a successful ChIP assay is the quality of the antibody, as some antibodies work poorly or not at all for ChIP. This limitation can be circumvented by epitope-tagging proteins of interest. For many epitope or other tags (GFP, HA, Flag or other), well-characterized antibodies are available. For experiments using such tagged lines, we recommend using a genomic construct, so that the protein of interest is expressed from the endogenous promoter, as well as testing for wild-type expression levels, and rescue of the null mutant phenotype with the tagging construct. For GFP-tagged constructs, it is also important to monitor fluorescence (proper folding of GFP).

III-E. Washes

Duration: 1.5 h

19. Place tubes on a magnetic stand. Remove supernatant from beads and reserve it for later verification of sonication.
- 20*. Wash 2 \times with 1 mL cold Low Salt Wash buffer. ^{NOTES}
- 21*. Wash 2 \times with 1 mL cold High Salt Wash buffer. ^{NOTES}
- 22*. Wash 2 \times with 1 mL cold 250mM LiCl Wash buffer. ^{NOTES}

- 23*. Wash 2 × with 1 mL cold 0.5 × TE. ^{NOTES}
24. Pipette off all liquid and add 50 µL Nuclei Lysis Buffer.
25. Incubate for 30 min at 65 °C in large incubator in Eppendorf tubes to separate the sample from the beads.
26. Remove and store the elution buffer, add another 50 µL elution buffer to beads and repeat heating and suspension. Combine both sets of elution buffer. Discard beads.

NOTES AND TROUBLESHOOTING

N20-23. Rotate all washes in a rotator for 5 min at 4 °C. Between washes place tubes on the magnetic stand until all magnetic beads have collected at the side of the tube and remove solution. Discard all washes.

III-F. Reverse crosslinking Duration: overnight

27. Add 82 µL Nuclei Lysis Buffer to reserved Input samples (Step 16) to bring them up to 100 µL.
28. Add 6 µL of 5 M NaCl to both Input and ChIP samples. Reverse crosslinks overnight at 65 °C.

III-G. DNA purification Duration: 1 h

29. Add 5 volumes (550 µL) Buffer PB to each tube.
30. Shake samples for 30 min at room temperature.
31. Load QIAquick spin columns with samples and centrifuge for 1 min at 13,200 rpm.
32. Reload flow-through and spin again. Discard flow-thru.
33. Add 750 µL Buffer PE to column and centrifuge 1 min at 13,200 rpm.
34. Discard flow-thru and spin again 1 min at 13,200 rpm.
35. Place column in a clean 1.5 mL tube and add 100 µL 0.5 × EB Buffer to center of column. Let sit 5 min.
36. Centrifuge at 13,200 rpm 1 min.
37. Reload flow-thru, let sit 5 min, and spin again for 1 min. Keep eluate.

STOPPING POINT:

The purified ChIP sample can be stored at -20 °C for at least one month. Do not dilute prior to storage.

III-H. Quantitative PCR and data analysis Duration: 3 h

- 38*. Proceed to quantitative PCR using gene specific primers. ^{NOTES}
- PCR is carried out in a final volume of 25 µL containing

12.5 µL Power SYBR Green PCR Master Mix (2×)

2 µL ChIP DNA template

0.5 µL primers (forward and reverse, 10 µM each)

9.5 µL sterile ddH₂O.

The PCR products are amplified with the following conditions: 95 4 °C for 10 min; 40 cycles of 95 4 °C for 15 sec and 60 4 °C for 1 min (Cycling stage); 95 4 °C for 15 sec, 60 4 °C for 1 min, and 95 4 °C for 15 sec (Melting Curve Stage). At least three technical replicates are needed. We include a 5-fold dilution series of input to be amplified by the same primer set to calculate % input. Four or more input dilutions are recommended. The eukaryotic initiation factor (*EIF4*), *ACTIN2*, and *TA3* are often used negative controls. For positive controls, use published data or test several candidate genes that could be regulated by the protein of interest. At least three independent biological replicate ChIP experiments should be performed. ^{NOTES}

NOTES AND TROUBLESHOOTING

N38. Test your primers on genomic DNA for efficient amplification prior to using them on ChIP reactions.

IV. OPTIMIZATION

If your ChIP-qPCR signal is very low relative to that obtained for input DNA (see ANTICIPATED RESULTS below), optimization of the ChIP protocol is required.

IV-A. Low abundance of transcription factor (Step 1, Step 35-37)

If your transcription factor of interest is low abundance (lower than 1 in 500,000 cDNA), we recommend using 600 mg tissues (more than 600 mg causes increased background) and we suggest preparing 2 biological replicates. After step 34, the two samples will be combined into one by using the eluate from one spin column for dual elution of the second sample.

IV-B. Insufficient reversal of the crosslink and subsequent loss of protein-associated DNA (Step 3)

A nice test for full crosslink reversal is the FAIRE (Formaldehyde Assisted Isolation of Regulatory Elements; Simon et al., 2012) method. Briefly, this technique relies on phenol chloroform extraction of sheared crosslinked DNA; only DNA not associated with proteins is recovered. Equal amounts of sheared genomic DNA, sheared crosslinked DNA and sheared crosslinked DNA after crosslink reversal should be subjected to FAIRE. The expected result is near 100 % recovery of the sheared genomic DNA and the sheared crosslinked DNA after crosslink reversal. By contrast the recovery of sheared crosslinked DNA should be very low. DNA recovery can be measured directly (by Qubit) or by qPCR of a single copy locus.

IV-C. Sonication efficiency (Step 12)

(See Figure 4). The sonicated DNA should be a smear with a ca. 500 bp maximum signal intensity. If the sonication was insufficient, you will see broader binding peak.

IV-D. Efficient IP (Step 17)

One reason for the low ChIP signal could be that insufficient antibody was used or that the antibody was of poor quality. Alternatively, the protein of interest may not be expressed at high levels in the tissue tested. ChIP reactions should be repeated with different amounts of antibody and antibody from different lots and providers. Of note, individual lots of polyclonal antisera can differ greatly in avidity and specificity, even from the same provider. This website reports functional testing antibodies commonly used in epigenetic research: <http://compbio.med.harvard.edu/antibodies/>. If the antibody to be tested also recognizes a protein that is more abundant than the protein of interest (for example both share the same epitope tag), we recommend first optimizing the antibody amount and source first with the more abundant protein. It is a good idea to test for protein recovery after IP by Western blotting and to check how much of the protein of interest remains in the supernatant after IP. To enrich for factors only present in a small number of cells, enhanced ChIP signal can be achieved by dissecting the tissue of interest, by using a genetic background that enriches for the tissue of interest (Kwon et al., 2005; Wu et al., 2012), or by employing cell or nuclei sorting (Birnbaum et al., 2005; Deal and Henikoff, 2010).

IV-E. Fresh solutions or reagents (Step 1-38)

Presence of a faulty solution or reagent besides the antibody of choice can significantly reduced ChIP efficacy (especially, formaldehyde). In this case, we recommend the user repeat a ChIP that has worked in the past (such as the H3K27me3 ChIP in Figure 3) and test if the same % input enrichment is observed.

IV-F. Optimize qPCR primer sets (Step 38)

In order to obtain high quality qPCR data, the primer sets need to meet several criteria (e.g., primer $T_m = 60 \pm 5^\circ\text{C}$, length 18 to 25 bases, GC content between 40 and 60 %). If the primer sets are not optimized, this may result in amplification artifacts and/or inaccurate quantification. To design primer sets, we recommend use of Primer3 (bioinfo.ut.ee/primer3-0.4.0/). Primer sets should be tested by performing qPCR with sonicated input DNA. The amplification efficiency can be improved considerably if the length of the amplified fragment is between 60 and 150 bp. The ChIP-qPCR should be in the linear range of amplification. To confirm that the primer sets amplify a single fragment of the correct size it is recommended to run the qPCR product on an agarose gel.

IV-G. Data normalization (Step 38)

The normalization methods often used for ChIP assay are (I) % input, and (II) fold enrichment. (I) In the % input method, the qPCR signals derived from the ChIP samples are divided by the qPCR signals derived from the input sample taken early during the ChIP procedure. Normalizing over input amplification gives a reliable readout of the ChIP efficacy. We recommend using this normalization method.

(II) If the ChIP signals for the genetic controls vary greatly between the different primer sets used, it may be advisable to use the fold enrichment method. In this method the signal obtained for the genetic control ChIP is set to one and the signal for the experimental ChIP is expressed as fold-increase above the genetic control signal.

V. ANTICIPATED RESULTS

Using this protocol, we obtain approximately 15 ng of good-quality genomic DNA from 300 to 500 mg of fresh tissue per immunoprecipitated sample. This amount of ChIP DNA is sufficient for 50 10 μL real-time PCRs, which allows us to monitor as many as 15 genomic regions plus the control locus in triplicate. The expected % input yield differs for the different types of factors that contact the genomic DNA. In general, we expect ca. 0.1-1 % input recovery for histone modification ChIP (Figure 3), 0.05-0.3 % input for transcription factors, and 0.009-0.002 % input for chromatin regulators (such as SPLAYED or BRAHMA). The difference in recovery is due to several variables, which include cell-type specificity of the factor of interest, its abundance in the nucleus, its proximity to the DNA, and its residence time on the DNA. This protocol has been used to perform ChIP-PCR, ChIP-qPCR, and ChIP-chip (William et al., 2004; Yamaguchi et al., 2009; Winter et al., 2011; Yamaguchi et al., 2013). We expect that it can be easily adapted for ChIP-seq.

ACKNOWLEDGEMENTS

We acknowledge the members of the Wagner lab for constructive discussions during the method development. We thank the members of the Penn Genomics Frontiers Institute ChIP class taught by N.Y. and D.W. for the data used to generate Figure 3. This research was supported by NSF grants IOS- 1257111 and NIH grant R01 GM64650-01.
