Mixing male lures results in an effective multispecies bait for trapping Bactrocera (Diptera: Tephritidae) fruit flies

Todd E. Shelly* and Rick S. Kurashima

The genus Bactrocera Macquart (Diptera: Tephritidae) contains invasive, polyphagous species that threaten fruit and vegetable production worldwide, and many countries maintain continuous surveillance programs to detect and monitor these pests (e.g., Jessup et al. 2007). These programs rely heavily on traps baited with male-specific lures, namely, methyl eugenol (ME, a natural plant product) and cue lure (CL, a synthetic compound), which attract several species within the genus (Jang & Light 1996). These lures are presented in separate traps, and it has long been recognized that traps baited with a blend of these liquid lures would greatly reduce costs of trap materials and servicing. Unfortunately, ME–CL mixtures generally show reduced performance relative to single-lure treatments. For example, Vargas et al. (2000) reported that traps baited with an ME–CL mixture captured similar numbers of the CL-responding species Bactrocera cucurbitae (Coquillett) as traps baited with CL alone but significantly fewer individuals of the ME-responding species Bactrocera dorsalis (Hendel) than traps baited with ME alone.

Recently, a solid dispenser or wafer (Farma Tech International, North Bend, Washington) containing ME and raspberry ketone (RK, a natural analogue of CL) has been found to perform as well as standard, single-lure presentations (Shelly 2010; Vargas et al. 2010). Given this result, the present study was undertaken to compare captures of B. cucurbitae and B. dorsalis male flies in traps baited with ME–RK mixtures versus traps baited with the single lures.

We assessed the attractiveness of 3 ME–RK mixtures that varied in the relative amounts of ME (a liquid) and RK (a powder). By weight, the 3 mixtures contained ME and RK in proportions of 85:15, 90:10, and 95:5. A toxicant (naled, a liquid) was then added to each mixture (5% by volume). Solutions were stirred thoroughly, and aliquots of 5 mL were applied to cotton wicks placed individually in perforated baskets and then placed inside Jackson traps (IAEA/FAO 2013). For the single-lure treatments, we placed 5 mL of ME or CL on cotton wicks. This basic protocol follows that of Bactrocera detection programs in California and Florida (IPRFFSP 2006).

All trapping was conducted in a coffee (Coffea arabica L.; Gentianales: Rubiaceae) field about 10 km southeast of Haleiwa, Oahu, Hawaii. Coffee is a host of B. dorsalis, and hosts of B. cucurbitae were abundant along the field’s perimeter. The 3 ME–RK mixtures were tested individually against ME and CL treatments in separate sampling intervals following the same protocol. Thirty trapping stations, separated by a minimum of 50 m, were established. At 15 stations, we placed 2 Jackson traps (2–3 m apart), one baited with ME and the other with CL. At the remaining 15 stations, we placed a single Jackson trap baited with an ME–RK mixture. All traps were hung directly on coffee plants in shaded locations 1.5 to 2.0 m above ground. Trapping was conducted every 2 wk over an 8 wk interval. During a sampling interval, traps operated for 24 h and were then returned to the laboratory, where the sticky inserts were removed and the flies identified by species and sex under a dissecting microscope. Traps, with lures still inside, were suspended in a covered, outdoor area near the laboratory for weathering until the next sampling period. The lure treatment used at a particular station was alternated between successive sampling events.

Raw data were log10 transformed, which yielded normal distributions in most cases (4 of 6; 2 species, 3 ME–RK mixtures), and analyzed using a 2-way ANOVA (with week and lure type as main effects). ANOVA using ranked data (Conover & Iman 1981) generated results identical to those obtained using raw data, indicating that the parametric analyses of raw data were sufficiently robust to accommodate the degree of non-normality present in a few cases.

For B. dorsalis (Fig. 1), lure type had a significant effect only for the comparison involving the 90:10 mixture (F1,140 = 20.1; P < 0.001), where traps containing the ME–RK blend captured more male flies than traps containing ME alone. Lure type had no detectable effect in tests with the 85:15 (F1,140 = 0.1; P = 0.73) or 95:5 (F1,140 = 3.3; P = 0.07) ME–RK mixture. Week had a significant effect in comparisons involving 90:10 (F1,140 = 20.1; P < 0.001) and 95:5 (F1,140 = 22.5; P < 0.001) ME–RK blends but not the 85:15 mixture (F1,140 = 1.6; P = 0.17). Where significant, temporal variation in male fly captures appeared to reflect non-monotonic decreases in trap catch (resulting, for example, from a decrease in lure attractiveness), but natural fluctuations in population size. The lure type × week interaction term was not significant in any of the tests (P > 0.05 in all 3 cases).

For B. cucurbitae (Fig. 2), lure type did not have a significant effect in any of the comparisons (85:15 blend: F1,140 = 0.7; P = 0.42; 90:10 blend: F1,140 = 0.1; P = 0.99; 95:5 blend: F1,140 = 2.5; P = 0.12). Week had a significant effect only in the comparison involving the 95:5 mixture (F1,140 = 21.1; P < 0.001) but not the 85:15 (F1,140 = 0.2; P = 0.95) or 90:10 blend (F1,140 = 1.9; P = 0.11). In the test involving the 95:5 ME–RK mixture, male fly captures showed a consistent decrease over time, but whether this trend reflected decreased lure attractiveness or natural population dynamics is unknown. The lure type × week interaction term was not significant in any of the tests (P > 0.05 in all cases).

Whereas previous studies (Vargas et al. 2000; Shelly et al. 2004) showed that liquid ME–CL mixtures attracted fewer B. dorsalis male flies than liquid ME alone, the present data revealed no inhibitory effect of liquid ME–granular RK solutions on B. dorsalis male fly captures, a result consistent with field trials involving solid dispensers (wafers) containing ME and RK in a single matrix (Shelly 2010; Vargas et al. 2010). Why ME mixtures containing RK, but not CL, effectively attract B. dorsalis male flies is unknown, but the present results suggest the ME–RK solution is an effective multispecies lure that could greatly reduce costs of tephritid trapping programs.

Detection of *Bactrocera* Macquart (Diptera: Tephritidae) fruit flies relies on male-specific lures, methyl eugenol and cue lure, which are presented singly in traps. We compared the efficacy of the standard single-lure treatments against mixtures of methyl eugenol and raspberry ketone (a natural analogue of cue lure) deployed in the same

**Summary**

Detection of *Bactrocera* Macquart (Diptera: Tephritidae) fruit flies relies on male-specific lures, methyl eugenol and cue lure, which are presented singly in traps. We compared the efficacy of the standard single-lure treatments against mixtures of methyl eugenol and raspberry ketone (a natural analogue of cue lure) deployed in the same.
No significant differences were found in captures of *Bactrocera cucurbitae* (Coquillett) or *B. dorsalis* (Hendel) male flies over 8 wk intervals between traps baited with a single lure and traps baited with any of the 3 mixtures tested.

Key Words: trapping; detection; semiochemical; invasive species

**Sumario**

La detección de moscas de la fruta *Bactrocera* (Diptera: Tephritidae) depende de los señuelos específicos para los machos, metil eugenol y el señuelo de referencia, que se presenta individualmente en las trampas. Se comparó la eficacia de los tratamientos estándar de un solo señuelo contra mezclas de metil eugenol y la cetona de frambuesa (un análogo natural del señuelo de referencia) puesto en la misma trampa. No se encontraron diferencias significativas en las capturas de machos de *Bactrocera cucurbitae* (Coquillett) o *B. dorsalis* (Hendel) por los intervalos de 8 semanas entre las trampas cebadas con un único señuelo y trampas cebadas con cualquiera de las 3 mezclas probadas.

Palabras Clave: atrapando; detección; semioquímicos; especies invasivas
