ABSTRACT: The goal of this study was to evaluate the susceptibility of North American opossums (Didelphis virginiana) to aerosol inoculation of Mycobacterium bovis at two dose levels in order to gain information on disease pathogenesis, fecal shedding of the organism, and the potential roles that opossums play in the spread of this disease in nature. Six opossums received high dose (1×10⁶ colony forming units (cfu) by aerosol inoculation; six opossums received low dose (1×10³ cfu) inoculation, and six opossums were sham-inoculated with sterile water and served as controls. Lungs were the most frequently infected tissues, with nine of 12 inoculated opossums positive for M. bovis on culture. Gross lesions consisted of multifocal pneumonia and enlarged lymph nodes. Microscopically, granulomatous pneumonia and granulomatous lymphadenitis associated with acid-fast bacilli were present in eight of 12 inoculated opossums. Fecal shedding was uncommon at both inoculation doses. While opossums were highly susceptible to aerosol inoculation of M. bovis, they did not become emaciated or develop widely disseminated lesions. From this study, opossums may transmit tuberculosis by aerosol infection to other opossums and may be less likely to become infected with M. bovis by oral and intra muscular inoculation (Diegel et al., 2002). This study utilized an aerosol inoculation method to more closely mimic natural droplet transmission and evaluated susceptibility to infection and fecal shedding at two different inoculation doses.

Eighteen wild-caught opossums with negative fecal cultures for Mycobacterium spp. were divided into three experimental groups. Six opossums were dosed with 1×10⁶ colony forming units (cfu) of M. bovis suspended in 2 ml of sterile water, six opossums were dosed with 1×10³ cfu M. bovis, and six were sham inoculated with 2 ml of sterile water. For inoculation,
opossums were tranquilized with intramuscular injection of 5 mg per kg tiletamine and zolazepam (Telazol®, Fort Dodge Laboratories, Fort Dodge, Iowa, USA; Stoskopf et al., 1999). Once tranquilized, opossums were placed in lateral recumbency inside a biosafety cabinet, their muzzles inserted into an anesthesia cone, and they were exposed to aerosol inoculum for 10 min (5 min lying in recumbency on each side). The inoculum was delivered through a commercial nebulizer (AeroVet® Aerosol Drug Delivery System, AeroVet Aerosol Products, Ontario, Canada), which was powered by a standard vacuum pump applying 15 pounds per square inch (PSI) room air.

Opossums were housed individually in Horsfal isolators with individual HEPA filters. Opossums were weighed at 2 wk intervals during the 90 day study. Fecal cultures for Mycobacterium spp. were collected on days 1, 30, and 60 post-inoculation (PI). Two opossums from each of the three experimental groups were tranquilized with Telazol®, then euthanized at days 30, 60, and 90 PI. Information recorded for each animal at necropsy included: total body weight and spleen, liver, and lung weights. All internal organs and subcutaneous lymph nodes were examined grossly during necropsy. The following tissues were collected in 10% buffered formalin for histopathologic evaluation: brain, nasal turbinate, cranial lymph nodes including tonsil, trachea, lungs, thoracic lymph nodes, heart, liver, spleen, kidney, gonad, adrenal gland, pancreas, small and large intestine, and mesenteric lymph nodes. All tissues were routinely processed, paraffin-embedded, sectioned at 3 µm and stained by both routine hematoxylin and eosin stain, as well as by Ziehl-Neelsen acid-fast stain for microscopic evaluation. Fresh tissues were pooled for mycobacterial isolation and identification techniques followed established protocols (Kent and Kubica, 1985; Butler et al., 1991; Reisner et al., 1994). All opossums in the three experimental groups gained body weight over the course of the study. All animals were active and exhibited good appetite throughout the study, and no animal developed external lesions associated with tuberculosis. All opossums were negative for Mycobacterium spp. by fecal culture prior to inoculation. Fecal samples from all animals were culture negative at day 1 and day 30 PI; only one low dose inoculated opossum was positive for M. bovis by fecal culture on day 60 PI.

Typical gross lesions in inoculated opossums included multifocal granulomatous pneumonia (five of 12 inoculated opossums) and enlarged thoracic lymph nodes (seven of 12 inoculated opossums) (Fig. 1). While one animal in each of the high and low dose groups exhibited splenomegaly, and one animal in each inoculated group exhibited hepatomegaly; no statistically significant difference was found in mean spleen or liver weights between the three experimental groups. However, the mean lung weight was statistically significantly higher (P<0.05) in the high dose group (45.3±17.1 gm) compared to both the low dose group (29.9±10.0 gm) and the sham-inoculated control group (24.0±5.4 gm). Statistical comparisons were made by Wilcoxon two-sample testing using SAS® software (Statistical Analysis Systems, Release 6.12, SAS Institute Inc., Cary, North Carolina, USA).

Microscopically, five of 12 inoculated opossums had granulomatous lymphadenitis with associated acid-fast bacilli; four opossums had lesions in their thoracic lymph nodes, and one opossum had a lesion in its mesenteric lymph node (Fig. 2). Eight of 12 inoculated opossums had granulomatous pneumonia associated with acid-fast bacilli typical of tuberculosis (Fig. 3); two of these animals were in the low dose group, while all six animals in the high dose group had this lesion. Granulo-
**FIGURE 1.** Lungs from a high dose *M. bovis* aerosol-inoculated opossum at 60 days post inoculation (PI). The lungs have dozens of scattered pale granulomas typical of pulmonary tuberculosis. Bar=1 cm.

**FIGURE 2.** Photomicrograph of mesenteric lymph node from a high dose *M. bovis* aerosol-inoculated opossum at 30 days PI. The central portion of the lymphoid follicle has been replaced by granulomatous inflammation composed of mixed infiltrates of lymphocytes and macrophages. H&E. Bar=50 μm.
matous inflammatory infiltrates consisted of macrophages, lymphocytes, and neutrophils, with rare multi-nucleated giant cells present in some cases. Non-tuberculosis-associated lesions present in all three experimental groups included endogenous lipid pneumonia in seven opossums and disseminated brucellosis in eight opossums.

Thoracic tissues were the most frequently infected with M. bovis. Nine of 12 inoculated opossums (three of six low-dose animals, six of six high-dose animals) had M. bovis positive cultures from pooled samples of lung and thoracic lymph nodes; all controls had negative thoracic tissue cultures. Only two inoculated opossums had positive cranial lymph node pooled cultures, and all control opossum cranial lymph node pools were culture negative. Two inoculated opossums had positive intestinal and mesenteric lymph node pool cultures, one low dose and one high dose animal, and all control opossum intestinal pools were culture negative. Finally, only one high dose opossum had a positive abdominal non-intestinal (liver, spleen, and kidney) pooled culture, while all low dose and control animals were culture negative.

The aerosol route of inoculation was highly successful in producing infected opossums, particularly in producing thoracic lesions. Furthermore, there was a noticeable dose effect, in that low dose animals had lower incidences of gross and microscopic lesions, lighter mean lung weight, and lower incidence of M. bovis positive cultures compared to the high dose animals. The higher mean lung weight of high dose inoculated animals was attributed to the marked granulomatous inflammatory infiltrate present in this group of animals. In spite of highly successful infection by the aerosol route, the inoculated opossums did not exhibit weight loss. Nor did the inoculated opossums exhibit clinical signs such as inappetance or depression. Finally, no mortality occurred during the 90 day course of the study. This is in marked contrast to experimental studies in brush-tail possums with high-dose (2x10^8 cfu) inoculation.
where high mortality rates occurred between 25 and 100 days PI (Jackson et al., 1995a). Even in low-dose (125 cfu) inoculation studies in brushtail possums, most animals exhibited inappetance, decreased body weight, and lethargy by 60 days PI (Buddle et al., 1994; Pfeiffer et al., 1994). Therefore, experimental aerosol inoculation of *M. bovis* in North American opossums would be a suitable model system to evaluate antibacterial agents for the treatment of tuberculosis, efficacy of tuberculosis vaccines, and more extended duration experiments to study long-term pathogenesis, organism shedding, and immunological responses.

Only one of 12 inoculated opossums was found to be shedding *M. bovis* in its feces at any PI culture period. Compared to previous experimental studies in opossums in which one of four orally-inoculated animals and three of four intramuscularly-inoculated animals shed *M. bovis* in their feces, there is a strikingly lower prevalence of fecal shedding in aerosol inoculated animals (Diegel et al., 2002). It appears that aerosol infected opossums are significantly less likely to shed *M. bovis* in their feces compared to other exposure routes, or that a more advanced stage of the disease is required before fecal shedding develops. This aerosol inoculation model in opossums produced fecal culture results similar to those reported in naturally infected brushtail possums in New Zealand, where positive fecal cultures of *M. bovis* were uncommon in cross-sectional sampling of wild possums (Jackson et al., 1995a).

That aerosol inoculation tends to produce lesions most frequently in the thoracic visera was not surprising. However, similar experimental studies using intratracheal inoculation in the brushtail possum at lower inoculation doses resulted in more widely disseminated lesions, significant losses in total body weight, and rapid deterioration of clinical signs (Buddle et al., 1994; Pfeiffer et al., 1994). One possible explanation for this disparity between study results is the fact that our aerosol delivery system more closely resembles natural airborne infection, which allows impaction of organisms on nasal turbinates, and clearance by the mucociliary apparatus in the airways. Many of the earlier experimental studies in brushtail possum studies utilized intratracheal inoculation which bypassed much of the natural defense mechanisms, likely resulting in a higher dose of infectious organism in the lungs. The abdominal non-intestinal viscera pool (liver, spleen, and kidney) was harvested to evaluate hematogenous spread of *M. bovis*, because positive cultures would indicate generalized infection (Jackson et al., 1995b). In this study, only one high dose animal had evidence of generalized infection, while generalized infections involving these tissues are frequently reported in brushtail possums following either natural or experimental infection (Buddle et al., 1994; Cooke et al., 1995; Jackson et al., 1995b; Pfeiffer et al., 1994). Therefore, the North American opossum appears significantly less susceptible to *M. bovis* infection than is the brushtail possum. The North American opossum tends to primarily develop pulmonary tuberculosis, while the brushtail possum develops rapidly progressive disseminated tuberculosis.

In naturally infected brushtail possums, development of subcutaneous lymphadenitis and subsequent draining fistulous tracts results in a much greater risk for transmitting *M. bovis* to other animal species (Jackson et al., 1995a). The combination of fistulous tracts, generalized debilitation of infected possums, and the curious nature of large ruminants has been documented as a major factor in the interspecies transmission of *M. bovis* in New Zealand (Patterson and Morris, 1995). However, our study found neither debilitation, nor any gross involvement of subcutaneous lymph nodes or fistulous tracts in infected opossums. These results suggest that North American opossums are at significantly lower risk to serve as a source of.
infection for cattle and cervidae than the brushtail possums. Opossums are still relatively susceptible to *M. bovis* infection, whether they are exposed by aerosols, ingestion, or intramuscular injection. This means that if tuberculosis is introduced into these animals in the wild, active infections can develop and aerosol spread might occur to other opossums, such as from a mother to her young. Other carnivores might be infected by feeding on opossums. Our surveillance in Michigan has found several wild opossums with naturally-occurring infections. Our studies to date suggest that while the North American opossum may potentially serve as a reservoir host species for *M. bovis* it does not play a major role in transmission of the organism to deer and cattle.

This study was funded in part by a grant from the United States Department of Agriculture, Animal and Plant Health Inspection Service, Veterinary Services, Tuberculosis Cooperative Agreements.
