BioOne Complete (complete.BioOne.org) is a full-text database of 200 subscribed and open-access titles in the biological, ecological, and environmental sciences published by nonprofit societies, associations, museums, institutions, and presses.

Your use of this PDF, the BioOne Complete website, and all posted and associated content indicates your acceptance of BioOne's Terms of Use, available at www.bioone.org/terms-of-use.

Usage of BioOne Complete content is strictly limited to personal, educational, and non - commercial use. Commercial inquiries or rights and permissions requests should be directed to the individual publisher as copyright holder.

BioOne sees sustainable scholarly publishing as an inherently collaborative enterprise connecting authors, nonprofit publishers, academic institutions, research libraries, and research funders in the common goal of maximizing access to critical research.

ELECTRICAL CAPACITANCE AS A PREDICTOR OF ROOT DRY WEIGHT IN SHRUB WILLOW (*SALIX*; SALICACEAE) PARENTS AND PROGENY¹

CRAIG H. CARLSON² AND LAWRENCE B. SMART^{2,3}

²Horticulture Section, School of Integrative Plant Science, Cornell University, New York State Agricultural Experiment Station, Geneva, New York 14456 USA

- *Premise of the study:* Root biomass is an important trait often disregarded in woody perennial selection due to the challenge and expense of accurately and efficiently measuring large populations. In this study, we aim to develop a simple method that can predict root dry weight within a diverse shrub willow (*Salix*) breeding population representing species hybrids and their parents using root electrical capacitance (REC).
- *Methods:* The REC method was tested on plants started from cuttings and grown in pots with potting mix in the greenhouse for 11 wk to assess the relationship of REC with 24 biomass traits and its usefulness in allometric models for root and stem dry biomass.
- *Results:* Strong linear and positive correlations were found between REC and root dry biomass ($r = 0.88$). The total proportion of variance of root and stem dry biomass explained by predictors in multiple regression was 85% and 69%, respectively. The relative importance of predictor variables in allometric models was dominated by the contribution of REC.
- *Discussion:* This work provides an efficient and nondestructive technique to indirectly quantify root biomass of genetically diverse shrub willow progeny, which has great promise for selection of genotypes with varying root biomass and for the accurate estimation of belowground carbon sequestration.

Key words: bioenergy; biomass; breeding; phenotype; selection; short-rotation coppice.

The measurement of belowground traits of woody perennials has been the subject of renewed interest in recent years, because root biomass and architecture are critical for drought tolerance and for long-term carbon sequestration (Ericsson et al., 1996). Measurement of root biomass is a tremendously difficult and painstaking task in woody perennial breeding programs, as it requires careful washing, filtering, drying, and weighing fine root tissues, and thus is often avoided. For decades, electrical capacitance has been used to estimate the aboveground biomass of herbaceous perennials (Currie et al., 1987) and forest plantations (Lekas et al., 1990), but few root electrical capacitance (REC) studies have focused on clonal woody perennial plants as a model for predicting root biomass. Previous work on the estimation of root biomass using the REC method has primarily focused on hydroponically grown seedlings (Rajkai et al., 2005; Repo et al., 2005; Cao et al., 2011; Dietrich et al., 2012; Cserenyés et al., 2013; Kormanek et al., 2015) or a limited number of genotypes (Whitlow et al., 1992; Pitre et al., 2010).

Dalton (1995) provided the first and most widely accepted conceptual model for using electrical capacitance as an in situ measurement for assessing root development. Electrical capacitance is measured in farads (F) and is considered the ability of a body (i.e., plant root tissue) to store an electrical charge, such that when charged with one coulomb (C) of energy, there is a potential difference of one volt (V), where $F = C/V$. His method assumes that root capacitance is equivalent to a parallel resistance-capacitance circuit formed by the interface between soil and water and the root surface; or simply, that roots are equivalent to cylindrical capacitors where the epidermis and xylem are external and internal electrodes, respectively. Capacitance is formed by the polarization and relaxation of root membranes, which promotes fluctuations in amplitude and phase of the AC signal (Repo et al., 2000). This root–soil interface exhibits a capacitance proportional to the size of the membranes.

What *exactly* REC measures is debatable. Using hydroponically grown barley seedlings, Dietrich et al. (2012) argued that capacitance is linearly correlated with the sum of root cross-sectional areas at the solution surface and inversely related to the distance between the plant electrode and the solution surface. Likewise, the capacitance of barley is not determined by actual root biomass but by the cross-sectional area of roots at the solution surface (Dietrich et al., 2013). The distinction between this model and Dalton's is that Dalton generalized roots to be cylindrical capacitors acting in parallel, whereas Dietrich argued that the capacitances of tissues along an unbranched root can be considered to be connected in series and the entire root system, in parallel. Although Repo et al. (2005) found a strong linear relationship between the cross-sectional area and the resistance of

the stem, there was no difference in the relationship between resistance and cross-sectional area with or without the roots attached. Ellis et al. (2013) found little evidence that capacitance alone could be related to root mass, but these measurements could be used together with approximations of average root tissue fresh density to estimate coarse root length.

Dietrich et al. (2012) provides good evidence to modify the conceptual framework of Dalton's original model, yet all analyses were based on fresh root mass of a hydroponically grown herbaceous annual. Compared to dry mass, wet mass can be extremely variable and heavily dependent on environmental factors (Lam et al., 2008) and is not an ideal estimate of root biomass for shrub willow. Furthermore, the compositional differences and developmental stage between seedling and mature, fully developed root systems cannot be ignored.

Here, we simply assume the Dalton model using a diverse breeding population of shrub willow (*Salix*; Salicaceae), with no assumptions concerning root morphology or architecture. Shrub willow has been bred as an energy crop in Europe since the early 1970s with the goal of producing fast-growing bioenergy feedstock cultivars that are high-yielding, genetically diverse, pest and disease resistant, and able to grow on marginal land without competing with food crops (Karp et al., 2011; Smart and Cameron, 2012). Shrub willow are dioecious riparian species commonly found near riverbanks and streambeds and are well adapted to the hypoxic conditions of wetlands (Kuzovkina et al., 2008). More than 350 species have been described in *Salix* L. (Argus, 2005; Lauron-Moreau et al., 2015) and have tremendous ecological amplitude, found within marginal and riparian habitats from the arctic plains to the subtropics (Kuzovkina et al., 2008). As the challenge to meet global energy objectives increases (Kriegler et al., 2014) along with global temperatures (Walther et al., 2002; Whiteman et al., 2013), the demand for low-input renewable bioproducts (Rose et al., 2014) gives shrub willow great potential as a competitive bioenergy feedstock for biomass production and conversion to biofuels to offset fossil fuel usage (Bonosi et al., 2013).

Our main objectives of this study were: (1) to investigate the relationship between electrical capacitance and root dry weight in diverse shrub willow families, (2) to contrast REC of parent genotypes and their hybrid progeny, (3) to study the relationship between REC and above- and belowground biomass traits, and (4) to evaluate the relative importance of REC in allometric models for the prediction of root and stem dry weight.

MATERIALS AND METHODS

Plant material—Parent genotypes and randomly chosen progeny of *Salix purpurea* L. ($2n = 2x = 38$), *S. miyabeana* Seemen ($2n = 4x = 76$), and *S. viminalis* L. ($2n = 2x = 38$) species crosses were grown from stem cuttings (20 cm) in 12-L plastic pots with peat moss–based potting mix (Fafard, Agawam, Massachusetts, USA) to evaluate growth traits under greenhouse conditions over an 11-wk period. Families consisted of 12 progeny individuals and their parents from diploid intraspecific *S. purpurea* F₁ and F₂ crosses, two reciprocal diploid interspecific crosses (*S. purpurea* × *S. viminalis*), three triploid interspecific crosses (*S. purpurea* × *S. miyabeana*, *S. miyabeana* × *S. viminalis*, and *S. viminalis* × *S. miyabeana*), and an intraspecific tetraploid cross of *S. miyabeana* for a total of 104 genotypes (Table 1). One exception is that one of the parents of the *S. miyabeana* family (SX64, male parent of 425) was not included. Plot was defined as a single cutting planted in a pot; pots were arranged in a randomized complete block design with four replicate blocks. Two blocks were located on benches in one greenhouse with the other two blocks in an adjacent greenhouse set for identical growing conditions. Supplemental greenhouse lighting was provided on a 14-h day:10-h night regimen with maximum daytime temperature of 26°C and a

nighttime temperature of 18°C. Beyond weekly applications of beneficial insects and mites for pest management, no pesticides were required, as there were no symptoms of biotic or abiotic stress on any plant material throughout the length of the study. Liquid fertilizer (Peter's 15-16-17 Peat-Lite Special; Scotts Miracle-Gro Company, Marysville, Ohio, USA) was applied weekly after week 4 according to manufacturer recommendations. The age of plants and the frequency of trait measurements is depicted in Table 2.

Root electrical capacitance—Root electrical capacitance was measured using a DCM3 digital capacitance meter (UEi Test Instruments, Beaverton, Oregon, USA) with conductance ranges of 200 pF to 20 mF, and a $\pm 1\%$ reading and digital accuracy below 2000 μ F. Custom-designed electrodes were attached to the capacitance meter as follows: the positive lead wire was connected to a 10-gauge (0.27 × 20 cm) solid copper wire, while the negative lead was connected to a 7.5 × 1.0 cm copper-plated gator clip. The copper wire attached to the positive lead of the capacitance meter was inserted 15 cm into the potting mix approximately 10 cm from the cutting, and the negative lead was clamped to the cutting 2 cm above the surface of the potting mix. Root electrical capacitance was measured approximately 2 h after pots were completely saturated with reverse-osmosis water immediately after harvesting aboveground biomass. To minimize within-plot variation, four readings were taken equidistant to the cutting and then averaged for each pot. The appropriate experimental nominal capacitance was determined to be 200 nF or 20 μ F (if REC >200 nF) at 820 and 82 Hz test frequencies, respectively.

Aboveground biomass traits—Starting approximately 7 d after planting, the vegetative phenology stage (PHE) of each plot was scored 7, 9, 11, 13, and 15 d after planting (DAP). Vegetative phenology was scored as six stages described as: stage (0) dormant axillary buds are tightly closed and covered by bud scales, (1) axillary buds begin to swell and change color, (2) generative buds burst with visible leaves, (3) leaves emerge and begin to unfold, (4) unfolded leaves begin expanding, and (5) at least two leaves are fully expanded.

Primary stems were defined as those emerging from dormant axillary buds and ≥ 6 cm in length. Secondary stems were defined as emerging from axillary buds on the primary stem from current-season growth (sylliptic) and were counted as the total number of secondary branches within each plot with a vegetative phenology stage ≥ 3 . The length of all stems ≥ 6 cm per plant was measured from the base of the primary stems at the original cutting surface to the distal shoot tip (the inner-whorl of the leaf primordia). Starting in the second week of the study until its termination, all primary stems were measured within each plot once a week over a period of nine weeks.

Mean stem length (MSL) per plant was the mean of individual stem lengths, and sum of stem length (SSL) was the sum of all primary stems measured for a plant. The diameter of each primary stem within a plot was measured at the base in the final week of the study using a digital caliper. The stem diameters were used to calculate mean stem area (MSA) for all of the stems on a plant, and all stem areas were summed to determine sum of stem area per plant (SSA). Only primary stems >20 cm in length were used to calculate stem traits. Stem and leaf biomass were harvested separately from each plot, dried in an oven to constant weight at 65°C, and weighed to determine stem dry weight (SDW) and leaf dry weight (LDW).

Leaf area (LFA) was determined using a portable leaf area meter (model no. CI-203; CID Bio-Science, Camas, Washington, USA). A representative leaf from each plot was scanned, then excised, dried to constant weight at 65°C, and weighed to obtain leaf dry weight. Petioles were excluded from leaf area and dry weight measurements. Specific leaf area (SLA) was calculated as the ratio of the total leaf area and dry weight as well as its inverse, leaf mass per area (LMA). As an indirect measurement of leaf chlorophyll and nitrogen content, leaves were measured using a SPAD 502 Chlorophyll Meter (Spectrum Technologies, Aurora, Illinois, USA). Four fully expanded leaves from the upper 25% of the canopy were measured and averaged for each plant at weeks 2, 4, 6, and 10.

Belowground biomass traits—Root biomass was harvested from a subset of 20 pots (2–3 unique individuals per family) that were selected from the 416 pots as representing a distribution of capacitance readings, ranging from 70.5 nF (clone 13X-425-110) to 283.8 nF (clone 13X-430-033). To assure the retrieval of fine root hairs, potting mix was washed from roots by first soaking root balls in water for 12 h without their pots, then rinsing them by hand repeatedly, and decanting into 2.4-mm and 1.0-mm aluminum test sieves. Root samples were considered appropriate for dry weight analysis when root biomass was visually free of debris. Root biomass and cuttings were separately dried in an oven and weighed to obtain root dry weight (RDW) and cutting dry weight (CDW). The base diameter and number of each primary root as well as the average distance

between secondary root primordia of primary roots were measured using an Absolute Digimatic digital caliper (model no. CD-6[™]CSX; Mitutoyo USA, Aurora, Illinois, USA).

Statistical analysis—All statistical analyses were performed in the statistical computing environment, R 3.2.2 (R Development Core Team, 2011). Traits (Table 2) were tested for paired associations ($\alpha = 0.05$) with REC using the `cor.test` function. To determine the best transformation of REC for the response variables, the Box-Cox procedure was used. Only SDW and LDW were found to be log-linear ($\lambda=0$) to REC; consequently, a log transformation of REC was performed in linear and multiple regressions for these traits. When significant differences were observed, Tukey’s studentized range test was used for family mean comparisons and significant differences.

Variance components were estimated using `lmer` in the package `lme4` (Bates et al., 2015) using the restricted maximum likelihood (REML) method. To analyze the effects of male, female, and male × female interactions, the following linear mixed model was used:

$$Y_{ijkl} = \mu + B_i + M_j + F_k + MF_{jk} + C(MF)_{l(jk)} + e_{ijkl}$$

where, Y_{ijkl} is the observed value, μ is the overall mean, B_i is the effect of block i , M_j is the effect of the male parent j , F_k is the effect of the female parent k , MF_{jk} is the interaction effect between male and female parent jk (i.e., family),

TABLE 2. List of biomass-related variables including their descriptions and units.

Trait abbreviation	Description	Units	Measured (WAP)
Aboveground			
SDW	Stem dry weight	g plant ⁻¹	11
SSL	Sum stem length	cm	2–11
MSL	Mean stem length	cm	2–11
MXL	Maximum stem length	cm	2–11
MSA	Mean stem area	cm ²	11
SSA	Sum stem area	cm ²	11
RGR	Relative growth rate	cm d ⁻¹	3–11
PSN	Primary stem number	#	11
ASN	Axial stem number	#	5, 10
LDW	Leaf dry weight	g plant ⁻¹	11
SPD	SPAD	SPAD units	2, 4, 10, 11
PHE	Vegetative phenology	0–5	2–3
MSD	Mean stem diameter	cm	11
SSD	Sum stem diameter	cm	11
LFA	Leaf area	cm ²	11
SLA	Specific leaf area	cm ² g ⁻¹	10
LMA	Leaf mass per area	g cm ⁻²	10
Belowground			
REC	Root electrical capacitance	nF	11
RDW	Root dry weight	g plant ⁻¹	11
CDIA	Cutting diameter	cm	11
CDW	Cutting dry weight	g plant ⁻¹	11
RDIA	Mean root diameter	cm	11
PRN	Primary root number	#	11
SRN	Secondary root number	#	11
TRN	Total root number	#	11

Note: WAP = weeks after planting.

$C(MF)_{l(jk)}$ is the effect of clone l within family, and e_{ijkl} is the random error. All effects except μ were considered random.

The general combining ability (GCA) or the effects of parents was extracted from this model to provide the relative phenotypic contributions of the male parent (M_j) and female parent (F_k) to family progeny. The deviation of progeny trait values relative to their parents (midparent heterosis [MPH]) was calculated for each family as $((F_1 \text{ progeny} - \text{midparent})/\text{midparent}) \times 100$. Family 425 was removed from MPH calculations because the male parent was not present.

Initial estimates of the predictive accuracy of RDW using REC (adjusted $R^2 = 0.77$, $P = 0.001$) were cross-validated via K -fold ($k = 5$) and leave-one-out ($N - 1$) methods ($R^2 = 0.71$, RMSE = 5.1) using the least-square estimates of model coefficients as well as the root mean squared error (RMSE) to determine the prediction loss of the model in the package `cvTools` (Alfons, 2012). To evaluate the total variance explained by each predictor variable in multiple linear regression analyses, Lindeman, Merenda, and Gold (LMG; Lindeman et al., 1980), First and Last, Genizi (Genizi, 1993), and Pratt (Pratt, 1987) metrics were used to order predictors and decompose R^2 in the `relaimpo` (Relative Importance for Linear Regression) package (Grömping, 2006). To assess which regressors are different in terms of relative importance, confidence intervals (CIs) were calculated using 1000 bootstrapped replicates (Bonferonni CI = 95%). Pratt and LMG indices were used to partition the additive properties of R^2 , calculated as the sum of their individual importance irrespective of the correlation among predictor variables. Correlations of above- and belowground biomass-related traits with REC and SDW were performed to rank predictors in multiple regression models. To avoid any potential issues with collinearity in downstream analysis, repeated trait measurements were reduced to a single representative measurement based on the proportion of model variance it explained. For instance, the third of five phenology measurements (12 DAP) and the sixth of nine stem length and stem number measurements (48 DAP) were chosen because they had the strongest correlation with REC and/or SDW.

Important predictors of RDW were selected from a total of 15 cutting and root traits from 20 individuals selected along the distribution of REC readings using stepwise regression (step Akaike Information Criterion [AIC], direction = both) of the linear model fit. Variable selection for SDW was conducted using common relative importance indexing methods. Confidence intervals for each model were produced using 1000 bootstrap replicates at a 95% level of significance. The LMG method is the most commonly used metric in multiple regression. With regard to ranking predictors based on their relative importance, Genizi and Pratt CIs were equivalent to the LMG method. Outcomes from the Genizi predictor ranking method were excluded, as both predictor importance and contributions were nearly identical to the LMG method. The Pratt index was selected to order predictor relative importance in multiple regression analyses because it explains the total variance as the sum of predictor R^2 .

RESULTS

Family variation in REC and biomass production—The means of REC significantly differed by up to 34% among the eight full-sib families (Fig. 1, Appendix S1). The triploid family 430 (*S. miyabeana* × *S. viminalis*) displayed the greatest REC means (182.8 nF), while the triploid family 415 (*S. purpurea* × *S. miyabeana*) has the lowest REC with a mean of 120.8 nF (Fig. 1, Appendix S1). The effect of clone within family accounted for a majority of the variance of REC. In addition, the effect of the female parent was almost twice that of the male parent.

Fig. 1. Root electrical capacitance (REC) family means and errors (\pm SE) of four replicates as well as their respective Tukey's honest significant difference (HSD) at a 95% level of confidence. Outlined box plots to the right of bars represent the corresponding midparent value (\pm SD) for the parents of each family. Midparent means within box plots are denoted by bold horizontal lines. The male parent of family 425 was not present in this trial, thus the midparent box plot of family 425 is not shown. The species pedigree of each family is abbreviated above family identifiers, where *pur* = *Salix purpurea*, *vim* = *S. viminalis*, and *miya* = *S. miyabeana*. The direction of the cross is designated as female parent \times male parent species.

Combinations of parents with high GCA values should theoretically produce progeny with high absolute trait values. In absolute terms, the *S. purpurea* female clone 94006 had the greatest GCA of all parents. Of the families analyzed, MPH for REC was observed in the families 421, 423, and 430 but not in families 082 (F₁ *S. purpurea* \times *S. purpurea*), 317 (F₂ *S. purpurea* \times *S. purpurea*), 415 (*S. purpurea* \times *S. miyabeana*), and 407 (*S. purpurea* \times *S. viminalis*) (Fig. 1). Because one of the parents of family 425 was not included, heterosis was not calculated for that family. The female and male *S. viminalis* (07-MBG-5027 and 'Jorr') and the female *S. miyabeana* (01-200-006) parent clones had the greatest GCA of family parents (Appendix S2) contributing to progeny REC. Midparent heterosis for REC was the most dramatic for interspecific crosses of these parents, i.e., families 430 ($t = 4.09$, $P < 0.001$) (01-200-006 \times 'Jorr'), 423 ($t = 3.56$, $P = 0.003$) (07-MBG-5027 \times 01-200-003), and 421 ($t = 2.59$, $P = 0.02$) (07-MBG-5027 \times 94,001) (Appendix S1).

Model selection and predictor comparison—For all traits analyzed, significant REC correlation coefficients ($P < 0.05$) ranged from 0.11 (SPAD) to 0.88 (RDW). The REC trait was positively correlated with many above- and belowground biomass traits (Table 2, Fig. 2). Aboveground traits that most strongly correlate with REC were SDW, LDW, SSL, and MSA (Table 3). Belowground traits that most strongly correlated with REC were RDW, CDW, and CDIA (Table 3). Owing to the significant contribution of REC and SRN predictor variables, the reduced model, $RDW \sim REC + CDIA + PRN + SRN$, explains a substantial portion of the variation in RDW (multiple $R^2 = 0.85$, $P < 0.001$) (Appendix S3). Relative importance metrics for SDW predictor variables did not vary greatly among model orderings (i.e., rank); in contrast to within-trait R^2 and bootstrapped CIs (boot = 1000, Bonferroni CI = 95%), the magnitude of the difference in variation explained in the predictors did vary sig-

nificantly (Fig. 3). The proportion of variance that could be explained using the seven predictors in the final allometric model, $SDW \sim REC + SSL + MSL + SSD + ASN + PSN + SPD$, was 68.5% (Appendix S4). A large proportion of the variance is explained by the relative individual contributions of REC ($R^2 = 0.42$), SSL ($R^2 = 0.14$), and MSL ($R^2 = 0.15$). When REC is not included as a predictor variable in multiple regression, only 55.9% of the variation in SDW could be explained by the remaining variables—a difference of 12.6%. In each model index, REC was found to be significantly different compared to all other predictor variables and explained the greatest proportion of variance in each model index.

DISCUSSION

There are a number of key traits that could be selected in shrub willow breeding programs if a rapid method for phenotyping root traits was available, including rate of rooting establishment, ability to compete with weeds, drought tolerance, and total carbon sequestration ability (Pacaldo et al., 2013). The partitioning of photoassimilate from foliage to stem and root biomass is largely dependent upon a complex network of photosynthetic and transport processes (Dickson, 1989; Ericsson et al., 1996), as well as other morphological and environmental factors (Samuelson and Kelly, 1996). Rather than assume that the root:shoot ratio is constant among segregating progeny, it is likely there are genotypic differences in the accumulation of root biomass in proportion to aboveground biomass. While it is true that the quantitative nature of REC does not offer direct insight into root morphology or architecture, the specific morphologically based variances in REC need not be known if it is still a good predictor of RDW.

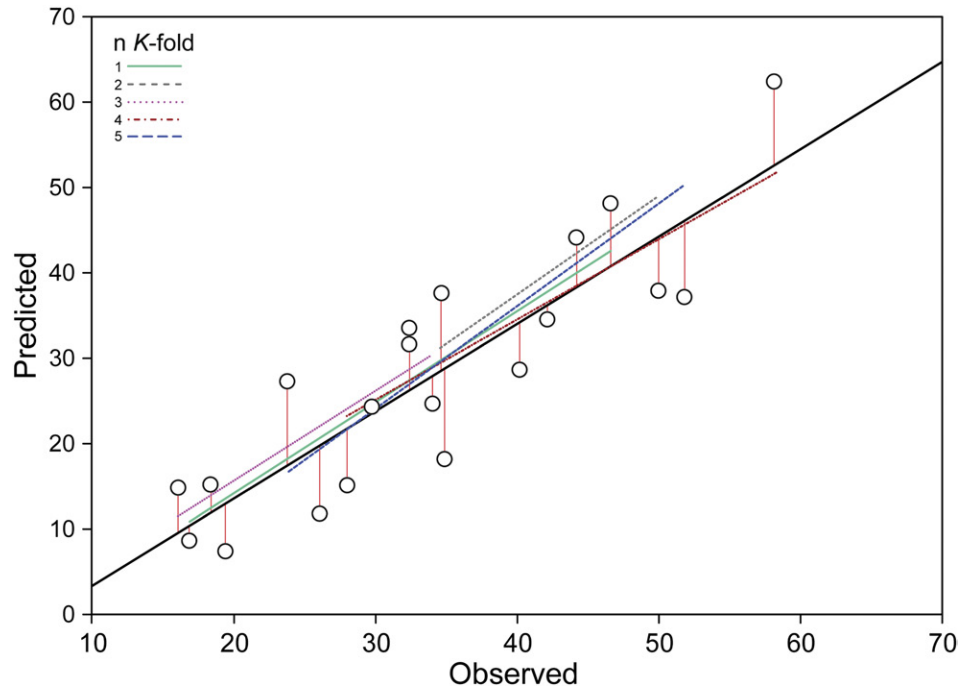

Fig. 2. Linear regression and *K*-fold cross-validation scatter plot of observed root dry weight biomass (RDW) predicted by root electrical capacitance (REC). The linear regression is $y = 0.21x - 6.91$ ($R^2 = 0.77$). Vertical red lines perpendicular to the regression line (solid black) represent the residual of the model fit, and colored lines represent *K*-fold sampling.

Increased vigor can be observed in intraspecific crosses of shrub willow, but the effect is generally more dramatic in the progeny of interspecific crosses (Serapiglia et al., 2014), especially

in triploid progeny derived from the hybridization of tetraploid and diploid parents (Serapiglia et al., 2015; Fabio et al., 2016). Likewise, we show that the interspecific families 421, 423, and

Fig. 3. Relative importance predictor index metrics for total stem dry weight biomass (SDW). Bar plots of each model index describe the variance explained as a percentage R^2 (summed to 100%). For each predictor, confidence intervals (CIs) were produced using 1000 bootstrap replicates at a 95% level of significance. Low percentages of total R^2 or CIs approaching zero describe unimportant variable contributions (e.g., SPD, “First” index method).

430 had significantly higher means for REC compared to their respective midparent values (Fig. 1, Appendix S1). For instance, the interspecific diploid family 421 is the result of a wide cross between parent species *S. viminalis* (sect. *Viminella* Ser.) and *S. purpurea* (sect. *Helix* Dumort.), whereas the interspecific triploid families 430 and 423 were derived from parents of contrasting ploidy-level as well as membership within sect. *Helix*, which may explain higher levels of midparent heterosis for this trait within these families. Neither the F_1 or F_2 intraspecific *S. purpurea* families displayed significant MPH for REC and were among the lowest performing families in this study.

We find that REC is highly correlated with RDW among all progeny and parent genotypes in this study, comparable to previous correlations found for one cultivar of shrub willow (*S. viminalis* × *S. schwerinii* E. L. Wolf ‘Olof’) (Pitre et al., 2010) and hybrid poplar (*Populus deltoides* W. Bartram ex Marshall × *P. nigra* L.) (Preston et al., 2004). Correlations of aboveground biomass traits with REC were similar to those of RDW, but the power to detect significant associations was weaker for RDW as a result of small sample size. Working with four commercial shrub willow cultivars, Cunniff et al. (2015) demonstrated LFA to have the strongest correlation with RDW ($R^2 = 0.49$) compared with other aboveground traits in a field setting. Besides the strong correlation of RDW with REC, RDW had strong linear and positive correlations with LDW and LMA, and a strong negative correlation with SLA (Table 3). Species with high LMA tend to have high leaf and root longevity (Ryser, 1996), which more efficiently conserve acquired nutrients and carbon,

thereby providing a competitive advantage for species with high LMA in nutrient-poor soils (Poorter et al., 2009). In this study, LFA was weakly correlated with RDW ($R^2 = 0.32$, $P = 0.16$) and only significantly correlated with REC ($R^2 = 0.40$, $P = 0.005$) in the diploid family 407 (*S. purpurea* × *S. viminalis*). The weak relationship between LFA and RDW can potentially be explained by high genotypic variances in carbon partitioning in leaves (Weraduwage et al., 2015) or a relatively small sample size.

Both REC and RDW strongly correlate to SDW. Early prediction of harvestable biomass yield is extremely important for the selection of high-performance woody perennial crops like shrub willow. If RDW contributes a substantial portion of SDW variance, it is exemplified by the REC technique. In all multiple regression model orderings, REC has shown to be the best predictor of SDW among all traits attributing to each model. Although LDW was strongly correlated with SDW ($R^2 = 0.81$, $P < 0.001$), it was excluded as a predictor variable in multiple regression analyses because it is a destructive measurement and not manageable to collect leaf biomass in a field setting. As far as we know, this is the first attempt using REC as a predictor variable in allometric models for yield.

Estimation of root biomass relative growth rates may be modeled from multitemporal data with minimal effort. The root system of shrub willow typically resides in the upper 20–30 cm of the soil and fine roots in the upper 10 cm (Pacaldo et al., 2013), which may find worthy implementation of REC as a long-term indicator of root development in research field trials. It may be that the proximal morphology of adventitious roots from the

cutting surface may provide the best explanation for the strong and positive correlation of REC with RDW. For the reason that shrub willow does not produce a large tap root from a cutting, it is possible that the proximity of the capacitance meter lead in the soil and the proximal root system provides a strong signal to the extent that a majority of the variance of root biomass can be explained by REC. However, comparisons of both seedlings and cuttings of shrub willow families must be conducted to determine if there are significant differences associated with root morphology impacting the prediction of RDW with REC. The effect of aboveground biomass on REC should be considered while conducting REC on a large-scale field study, and curves must be recalibrated accordingly. For the reason that aboveground biomass was harvested prior to taking REC measurements in this study, any confounding factors that may have been introduced into analyses were avoided. For instance, the difficulty of maintaining equivalent moisture content across genotypes is relative to the transpiration rate of respective genotypes, which were extremely diverse. Because the moisture content needed to be stable across plots, as noted in Dalton (1995), REC was measured after aboveground biomass was harvested, ensuring minimal water loss from pots over time. In the application of REC to the measurement of a large-scale field experiment, one would also need to measure moisture content adjacent to each REC measurement to use as a covariate in order to account for error associated with local variation in soil moisture content.

In addition to estimating RDW, there is also potential to investigate the relationship of REC with the occurrence and distribution of ectomycorrhizal and arbuscular mycorrhizal populations among short-rotation plantations and natural stands of shrub willow (Dhillion, 1994; Cseresnyés et al., 2013). Repo et al. (2016) implemented a PC-based method using electrical impedance spectra to assess the hardiness of mycorrhizal and nonmycorrhizal roots of Scots pine seedlings. Although there were no significant differences due to mycorrhizal treatments, Repo et al. (2016) found differences between treatment temperatures. Whether the accumulation of mycorrhizae is genotype-specific or impacts REC (Cseresnyés et al., 2016) in *Salix* spp. has not yet been characterized. It would be worthwhile to measure REC and sample mycorrhizae concurrently in a field setting to analyze the effects of altered environmental conditions on root growth and biomass yield.

The REC method provides an efficient, reproducible, and nondestructive alternative to more traditional “shovel-omics” techniques. However, the efficiency of REC must still be improved and the equipment itself scaled up to withstand heterogeneous soil profiles and thick stems on stools with multiple stems of mature plants in the field. For instance, Ellis et al. (2013) used the electrical capacitance 4T method (resistor and capacitor in series) as an indicator of root length in *Pinus* L., *Eucalyptus* L'Hér., and *Corymbia* K. D. Hill & L. A. S. Johnson forest tree plantations, resolving capacitance somewhat related to root mass within species but a poor indicator of diameter at breast height, root mass, or root length across species, age, or sites. In this study, we selected a relatively small sample size for validation of REC and RDW because of the rigor and time expense associated with carefully washing and retrieving fine and coarse roots from mature root masses in a short period of time. Only a few days after harvesting stem and leaf biomass from pots, new shoots began to emerge from their stools. Moreover, washing root samples over a one- or two-week period could introduce unwanted error into statistical analyses, thereby impacting

the relationship between REC collected at harvest and RDW, as well as correlations with morphological and physiological traits collected at the termination of the study. Technological improvements in field-based root phenotyping (Rautenbach et al., 2013; Meister et al., 2014) will hopefully allow for high-throughput quantification of root architecture and biomass at a reasonable efficiency and cost.

Compared to annual crops, it is likely that the electrical capacitances of perennial shrub willows will change over time as a result of root suberization, repeated coppicing, and seasonal variation of biotic and abiotic stressors. As implied, future work must be accomplished to determine if the strong relationship between REC and biomass-related traits on second- and third-year growth are equally as strong as in the first year. It is likely that over multiple coppice cycles, environment will play an important role in determining the genotypic stability of this trait in shrub willow. Nevertheless, the strength of REC prediction estimates of above- and belowground dry biomass is sufficient to conclude that it is not only valuable but is adaptable across *Salix* species, ploidy level, and hybrid pedigree.
