**ABSTRACT**

A new parasitic fungus, *Laboulbenia curtonoti* sp. n., associated with the endemic Madagascan fly *Curtonotum balachowskyi* Tsacas (Diptera: Curtonotidae), is described and figured. The new species is one of the very few Laboulbeniales which penetrate the insect’s cuticle by means of more-or-less developed rhizoids. A brief review of the 23 species of the genus *Laboulbenia* associated with Diptera is presented in a tabulated form.

**KEY WORDS:** Ascomycota, Curtonotidae, *Curtonotum balachowskyi*, Diptera, Laboulbeniales, Madagascar, new species, parasitic fungi, entomopathology, review.

**INTRODUCTION**

Laboulbeniales is a large group of ascomycete fungi which complete their entire lifecycle on living arthropods. Most are found on insects, but a few are known to parasitise mites and millipedes. These fungi are chiefly ectoparasitic, but a small number of the nearly 2,000 described species penetrate the insect’s cuticle by means of more-or-less developed rhizoids.

With almost 600 described species, the genus *Laboulbenia* is by far the largest among the Laboulbeniales (Rossi 2011). The number of species of *Laboulbenia* parasitic on the Diptera is, however, relatively small, only 23 having been described to date. These are reported from the dipterous families Celyphidae, Curtonotidae (as Drosophilidae), Chloropidae, Diopsidae, Lauxaniidae, Psilidae, Richardiidae, Tephritidae and various unidentified flies (Balazuc 1980; Lee & Majewski 1986; Rossi & Kotrba 2004; Rossi & Ponziani 2008; Rossi 1986, 1987; Thaxter 1901, 1902, 1917, 1918). A review of all previous records of *Laboulbenia* spp. associated with the Diptera is presented in tabulated form below (Table 1). Included names are updated, although some familial names were not specified in the original publications and some may represent misidentifications. It should be borne in mind that about half of the listed associations represent records from the African continent. It is also noteworthy that only a single fungal species, *Laboulbenia diopsidis* Thaxt., has subsequently been recorded after its original description. This does not represent evidence of rarity, but rather bears witness to the scarcity of research done in this field.

During the course of an ongoing revision of Madagascan *Curtonotum* Macquart, 1844 by A. Kirk-Spriggs, numerous specimens of the Malagasy endemic species *Curtonotum balachowskyi* Tsacas, 1974, were discovered parasitised by a fungus (e.g., Figs 1, 2). Further examination revealed that this parasite represents a new species of the genus *Laboulbenia*, which is described herein.

MATERIAL AND METHODS

Insects bearing Laboulbeniales were found in samples preserved in 95% ethanol, resulting from Mike Irwin’s *Arthropod Survey of Madagascar’s Protected Areas*, on loan from the California Academy of Sciences, USA (CASC). Thalli were carefully removed from the hosts with a size 3 insect pin. Permanent microscope slides of fungi were prepared following the method described by Benjamin (1971), using Amann’s solution, which is a mixture of glycerol, phenol and lactic acid, as mounting medium; cover slips were ringed with transparent nail varnish.

Slides of the type series are preserved in the Botanical Museum of Florence, Italy (FI) except for the isotype, which is deposited at the National Museum, Bloemfontein, South Africa (BMSA).

TAXONOMY

Order Laboulbeniales Lindau, 1898
Genus *Laboulbenia* Mont. & C.P. Robin, 1853

*Laboulbenia curtonoti* sp. n.

Figs 1–5

Etymology: The specific epithet *curtonoti* is derived from the name of the host insect (*Curtonotum*).

Description:

Cell I subspherical, partially to entirely inserted within host’s integument; thallus penetrating beneath integument with large haustorium (rhizomycelium). Cell II subhyaline, forming elongated stalk of uniform diameter throughout, only slightly enlarged apically. Stalk-cell of appendage (cells III+IV+V) greyish, about 1.5× longer than broad, its upper third free, although often in contact with base of perithecium; surface of upper, outer portion finely striate. Insertion cell dark, but not opaque, distinctly narrower than stalk-cell of appendage. Outer appendage greyish, with large basal cell bulging externally, followed by series of 3 or 4 gradually narrowing, superimposed cells, bearing dense tuft of elongate, brownish antheridia on inner side. Inner appendage consisting of small
Figs 1–5. (1, 2) Curtonotum balachowskyi Tsacas (Madagascar) bearing Laboulbenia curtonoti sp. n.: (1) habitus lateral (arrow indicates cluster of parasitic fungi on abdominal sternites); (2) same, detail (bulges of the insect’s integument are clearly visible at the base of the thalli, caused by the spherical basal cells). (3–5) Laboulbenia curtonoti sp. n.: (3) cluster of thalli; (4) appendage; (5) single thallus (a portion of the large haustorium penetrating the host’s abdomen is visible). Scale bar: Figs 1, 2 not to scale; Fig. 3, 650 μm; Fig. 4, 120 μm; Fig. 5, 500 μm.
basal cell giving rise on either side to very short branchlets, bearing apically crown of antheridia; in older specimens antheridia replaced by slender, hyaline, curved, sterile appendages, which barely reach half the height of perithecium. Stalk-cell of perithecium (cell VI) greyish, about as long as maximum width, its surface inconspicuously striate, separated from cell below by distinctly oblique septum. Perithecial venter free, blackish brown, ovoid, wall cells slightly twisted. Neck abruptly constricted, greyish, relatively short, distinctly curved, bearing two symmetrical, rounded prominences on inner (dorsal) side and smaller and paler bulge on outer side. Tip pale grey, also bearing three prominences positioned above those of neck; two inner ones hemispherical, surmounted by two small, erect, parallel, finger-like lips; outer one larger and less protruding, giving rise to two large, hyaline, slightly diverging, pointed, horn-like lips. Total length (from insect cuticle) 410–520 μm, ascospores 55 μm.

Holotype: MADAGASCAR: Majunga Prov.: Maintirano District, Asondroda dry forest 15 km N of Maintirano, 17°57.92’S:44°2.13’E, 200 ft [61 m], Malaise trap, 31.xii.2007–7.i.2008, M. Irwin & R. Harin’Hala, on the underside of the abdomen of Curtonotum balachowskyi Tsacas (Diptera: Curtonotidae), No. 3510a (FI).

Isotype: same data as the holotype, No. 3510b (BMSA).

Paratypes: MADAGASCAR: Majunga Prov.: Same data as the type, No. 3486; Besalampy District, Macrofotofa palm forest 17 km W of Besalampy, 16°43.30’S:44°25.42’E, 35 ft [11 m], Malaise trap, 19–26.xi.2007, M. Irwin & R. Harin’Hala, Nos. 3540 & 3546 (FI).

DISCUSSION

The small group of species of Laboulbenia parasitic on Diptera is paraphyletic. From the morphological standpoint it can be divided in three groups: one in which cells III, IV and V are distinct; one with these cells undivided; and one with a distinct cell V and cells III+IV fused together.

The very peculiar distal portion of the perithecium of Laboulbenia curtonoti sp. n., with the two large lips resembling the ears of a donkey, makes it possible to immediately distinguish it from all other species of the genus. The only species to which it can eventually be compared is L. dahlii (Thaxt.) Thaxt. (= Ceraiomyces dahlii Thaxt.), described from an unidentified “flower fly” from New Britain (Thaxter 1901). This latter parasite also penetrates the host with a long haustorium and shares the undivided stalk cell of the appendage, but differs from L. curtonoti in almost every other respect.

Preservation for extended periods in 95% ethanol, as these specimens had been, results in host insects becoming stiff and brittle, and as a result, it was not possible to extract the penetrating haustorium intact. It was possible, however, to observe that the basal portion of the haustorium is still quite large (diameter ca 30 μm) and undivided after 420 μm. From this it can be inferred that it is long and ramified in the distal portion as in L. dahlii (Thaxter 1908, pl. XLIII, fig. 4).

From preserved museum specimens it is also impossible to ascertain the degree of damage caused by the parasite to its host. Experimental studies undertaken with Stigmatomyces ceratophorus Whisler indicated that the life span of its host, the fly Fannia canicularis (L.), was not influenced by the presence of Laboulbeniales (Whisler 1968). This example provides only limited evidence, however, as S. ceratophorus is a “pure” ectoparasite and flies reared under experimental condition are not subject to predator pressure or food shortages. It can be assumed in the present case that the presence of large haustoria of L. curtonoti sp. n. may be detrimental to the host, especially when these occur in critical numbers on a single host fly (Fig. 3).

</table>

Three additional species of *Laboulbenia* have been reported on flies of the family Curtonotidae. These fungi, which were all found on unidentified species of *Cyrtoma* Séguy sensu lato (as *Cyrtoma* [sic!]), are *L. cyrtomatis* Balazuc (Senegal), *L. matilei* Balazuc (Central African Republic), and *L. tsacasii* Balazuc (KwaZulu-Natal Province, South Africa) (Balazuc 1980). Besides having a very different perithecial neck and tip, the last-named three species also differ from *L. curtonoti* in having different appendages and a “normal” basal cell (cell I), bearing the “usual” black foot at the base, not penetrating the host.
ACKNOWLEDGMENTS

Specimens used in this study were kindly loaned by N. Penny (CASC). These specimens were sorted in Sacramento, USA, by D. Woods and S.D. Gaimari.
