Abstract

Diatoms were found in late Holocene age ice-core samples recovered from the Quelccaya Summit Dome in the tropical Andes of Peru and were imaged by environmental scanning electron microscopy and identified. Freshwater diatoms in the genera *Hantzschia*, *Pinnularia*, and *Aulacoseira* were the most common taxa in the samples and indicate a freshwater source for the material, which also is suggested by the presence of the freshwater alga *Volvox*. The overall species composition of the diatoms suggests that the majority of taxa originated from a high-elevation lake or wetland in the cordillera surrounding the ice cap. The abundant diatom valves, up to 70 μm in size, likely were transported to the ice via wind.

Introduction

The analysis of ice cores from glaciers and ice caps in polar and alpine regions of the world has generated evidence of climate and environmental change associated with both natural and anthropogenic activities (Thompson et al., 2006). In addition to soluble isotopic and chemical evidence of changes in climate and atmospheric chemistry, ice cores also contain particulate material of both inorganic and biogenic origins that can provide insight into changes in land-surface cover and dynamics, including changes in dust production, biomass burning, and volcanic activity. Particulates trapped in ice also may reflect changes in atmospheric circulation patterns that affect long-distance transport of compounds from the continents or marine realm and their incorporation into glacial ice. In polar and high-latitude ice cores, the biological remains of microbes, including diatoms and other algae, have been reported in significant concentrations in glacier ice. In Greenland ice cores, for example, peaks in freshwater diatom concentrations are correlated with peaks in dust, suggesting that the diatoms were transported to the ice with dust from distant continental sources (Gayle et al., 1998; Donarummo et al., 2003). In various Antarctic ice cores, both freshwater and marine taxa have been identified and similarly attributed to eolian deposition (Burckle et al., 1988; Kellogg and Kellogg, 1996; Barrett, 2013).

The occurrence of diatoms and other microbes in glacier ice not only provides information about changes in source materials and their transport but also potentially provides useful information about the extent to which microorganisms are dispersed, which is central to understanding microbial biogeography (Fontaneto, 2011). Commonly it is assumed that microbes are widely dispersed (Fenchel and Finlay, 2004), yet many taxa have restricted rather than cosmopolitan distributions, suggestive of some sort of dispersal limitation (Telford et al., 2006; Boo et al., 2010). Contemporary studies of Antarctic snow show eolian dispersal of diatoms from marine sources over distances of 50 km (Budgeon et al., 2012) and have documented transport of centric diatoms up to 40 μm in diameter and pennate taxa >100 μm (McKay et al., 2008), although there is no evidence that these cells were viable during transit or at deposition.

The Quelccaya Ice Cap (13°56'S; 70°50'W, 5670 m a.s.l.) is located in the tropical Andes of southern Peru. During scanning electron microscope (SEM) analysis (Goldstein et al., 1992) of an ice core from the Quelccaya Summit Dome (QSD) for novel carbon nanomaterials derived from the burning of fossil fuels or through natural sources, we were surprised to find that the glacier ice was replete with freshwater diatoms. Although wind-blown diatoms carried in dust have been found in polar and high-latitude glaciers and ice caps (Harper and McKay, 2010), there are no prior reports of diatoms in glacial ice from tropical regions. In this article, we present SEM images and identifications of diatoms recovered from three core depths in the Quelccaya Summit Dome and make preliminary observations about their source and transport.

Diatom studies in tropical South America, particularly the tropical Andes, have a long and rich tradition extending back to the early 20th century, including explorations by Frenguellli (Frenguellli, 1939), the Percy Sladen Expedition (Tutin, 1940), and the Catherwood Expedition (Patrick, 1966). More recent studies include a flora of the entire Andean cordillera (Rumich and Lange-Bertalot, 2000) and various local investigations of specific diatom groups or habitats (Theriot et al., 1985; Tapia et al., 2004; Díaz and Maldina, 2005; Morales and Vis, 2007; Morales et al., 2012; Blasco et al., 2013; Montoya-Morena et al., 2013; Morales et al., 2014). Yet given the diverse range of habitats and the ext-
tensive area, the flora of the tropical Andes remains poorly
documented, and only a few modern studies include document-
ation of the diatoms using modern advances in imaging
technology.

Methods

The samples reported on here are from an ice core collected in
2003 from the QSD, which was preserved at –30 °C until analysis
(Thompson et al., 2013). The samples imaged by SEM were light
brown filtrate spots ~1.5 cm in diameter on SiO\textsubscript{2} filter paper. Sec-
ctions of analyte-bearing filter paper were mounted without further
modification. Cylindrical fibers observed in the SEM images are
the SiO\textsubscript{2} filter material.

Samples evaluated in this work are identified as QSD1, QSD2, and QSD3 from core depths (and ages) of 146.23–
146.80 m (A.D. 1161–1176 ± 3 yr), 156.22–156.94 m (A.D. 807–837 ± 5 yr), and 163.88–164.98 m (A.D. 460–511 ± 10 yr),
respectively. The ages of the upper samples were based on layer
counting in sections of the core to ~160 m (A.D. 683) (Thomp-
son et al., 2000). The high annual accumulation rate (~1200 mm
w.e. per year) and distinct seasonality of precipitation result in
seasonal variations in mineral dust and stable isotopes of oxy-
gen (\(\delta^{18}O\)), as well as visible annual dust layers, which enable
establishment of accurate annual layer counting over much of
the core. These dry season dust bands also are visible on a cre-
vasse wall of the Quelccaya ice cap (Thompson et al., 2013).
The seasonality of the insoluble dust concentrations remains
easily detectable with depth, even as the thinning becomes ex-
ponential. However, seasonal variations in \(\delta^{18}O\) become muted
by diffusion with increasing depth. Thus, in the lower portions
of the core, the ages were determined using a polynomial fit to
the age/depth relationship, which gave a bottom date for the
core of A.D. 226.

An FEI Quanta 400 environmental scanning electron mi-
roscope (ESEM) (Hillsboro, Oregon) was operated at 20 kV
in wet mode (2–3 torr H\textsubscript{2}O). The ESEM was equipped with a
EDAX\textsuperscript{TM} (Trenton, New Jersey) energy dispersive spectrometer
(EDS) fitted with a Super UTW\textsuperscript{TM} 0.3 nm window, and a Si\textsubscript{Li}
detector was operated in “spot” mode, utilizing 60 live second
acquisition periods with dead times of ~25%. Quantitative el-
mental analysis utilized the ZAF method (Goldstein et al.,
1992). Elemental compositions are reported in atomic percent.

Diatom identifications of the SEM images were made with
reference to regional floras (Rumich and Lange-Bertalot, 2000;
Metzeltin, 2007; Blanco et al., 2013), as well as European (Kram-
(Patrick and Reimer, 1966; Camburn and Charles, 2000; Spaulding
et al., 2010) floras.

Results and Discussion

The discovery of diatoms in the ice-core samples was a seren-
dipitous by-product of SEM imaging of samples for carbon nano-
materials, and hence the observations are neither quantitative
nor exhaustive. Some diatoms were obscured in the filter paper matrix,
and some were broken and not imaged. As a result, all possible
species in the samples may not be presented in this assessment, and
the data presented should be considered a sampling of the material
rather than a statistically valid cross section. Nonetheless, the sam-
ples furnish useful information on the size range of diatoms trans-
ported in high-elevation settings, such as the tropical Andes, and
the species composition provides some clues to possible source
regions of the material.

Particle size in the analyzed samples ranged from 10s of nm
to 10s of \(\mu\)m. The particle density was estimated to be 1000s of
particles per ice core liter, while diatom counts were in the range
of 250–500 valves per ice core liter. The diatoms in the ice samples
were small to moderate in size relative to the typical distribution
of freshwater diatoms and ranged from 10–70 \(\mu\)m in length and 3–16
\(\mu\)m in width. The pennate diatoms in QSD2 had the broadest range
in size, whereas valves in QS3 were typically the smallest.

Three diatom genera (\textit{Pinnularia}, \textit{Hantzschia}, \textit{Aulacoseira})
were common and frequently observed in the samples (Figs. 1 and
2). \textit{Pinnularia borealis} was the most common taxon overall, and
\textit{Hantzschia amphioxys} and \textit{Aulacoseira} also occurred in each sam-
ple. These common taxa also are found in ice cores from polar and
high-latitude regions where diatoms have been observed and have
been associated with long-distance eolian transport (Donarummo
et al., 2003; Harper and McKay, 2010; Papina et al., 2013). Ad-
ditional diatom fragments observed in QSD1, perhaps unique to
QSD1, were indistinct and did not permit definitive identification.
Figures 3 and 4 illustrate pennate diatoms apparently unique to
samples QSD2 and QSD3, respectively.

The ecological affinities of the diatoms suggest that the valves
originated from freshwater lakes, wetlands, or wet soils. The fresh-
water inference is supported by the presence of *Volvox*, a green freshwater alga (Maberly et al., 1994) that was observed in QSD2 and QSD3 (Fig. 5, part A). The majority of other taxa in the samples suggest that the source freshwaters for the diatoms had low alkalinity and low nutrient concentrations. In particular, *Brachysira vitrea*, *Eunotia* sp., *Stauroneis* sp., and *Aulacoseira alpigena* are typical of fresh clearwater lakes that have low alkalinity (Camburn and Charles, 2000). *Aulacoseira* species often are planktic and occur during periods when the water column is not thermally stratified as a result of some combination of cool temperatures, strong winds, and/or shallow depth. In some cases, *Aulacoseira* species are tychoplanktic and grow in chains attached to shallow-water substrates, including plants, rocks, and mud. Among the other taxa, *Hantzschia amphioxys* is an aerophilous species that grows in wet soils or other subaerial habitats, and *Pinnularia borealis* is a common benthic taxon that is found in shallow flowing or standing waters, as well as in subaerial habitats, such as wet soils, mosses, or rock substrates. One likely scenario is that the diatoms found in the Quelccaya ice originated in nearby high-elevation lakes or wetlands, which are abundant on the slopes surrounding the ice cap. The proximate location is suggested by the abundance of diatoms in the analyzed samples and by the presence of taxa characteristic of alpine lakes and wetlands, such as *Brachysira vitrea*, *Eunotia* sp., *Stauroneis* sp., and *Aulacoseira alpigena*. In addition, the preservation of the valves is generally excellent, which suggests the transport of recently deposited material from a lake or wetland, rather than long-distance transport of dust from older exposed sources, such as the southern Altiplano (Gaiero et al., 2013). Yet, two of the taxa (*Hantzschia amphioxys*, *Pinnularia borealis*) have been reported in global dust sources; thus, long-distance dispersal from a distant source for some of the valves cannot be ruled out.

In addition to the diatoms, the filtrate samples included numerous discrete aluminosilicate particles and aggregates that contain C, Ca, Fe, K, Mg, P, Na, Ti, as well as non-diatomaceous silica structures that may have biological origins. Morphologically and elementally the filtrates were similar across all samples. Excluding a few Fe-bearing aggregates, only three non-diatomaceous particles with a recognizable crystal form were larger than 1 μm. This suggests the predominance of particles with inorganic origins that have not experienced pressures and temperatures adequate for crystallization. Thus, the particles likely do not have origins deep within the earth, for example from volcanic eruptions, an observation that is consistent with the hypothesis of materials transported to the ice from surface deposits by wind.

**FIGURE 2.** *Aulacoseira* valves (centric diatoms) observed in (A–C) QSD1, (D–F) QSD2, and (G–I) QSD3. Parts A, D, and F–I are *Aulacoseira alpigena*; others are *Aulacoseira* sp.
Electron beam transparent high-carbon content masses (ETCM, Fig. 5, part B) and other unidentified, but highly structured, silicate objects (not shown) also were observed in the samples. ETCM material was occasionally associated with diatoms, resulting in diffuse images, and the electron transparency of these carbon masses results in significant SiO₂ contributions from the silica filter paper to the EDS spectra. A quantitative carbon content of these objects could not be determined, but with the substrate contribution to the EDS spectra, these masses still returned >50% carbon. Particles in general, including diatoms, returned

up to 10% carbon, whereas EDS spectra from a Si test wafer did not return a carbon signal. Two large tubes measuring ~85 μm × 30 μm in diameter were shown to contain 60% carbon (Fig. 5, part C) and likely have a biological origin. No other well-defined, high carbon content particles were observed.

Conclusions

Diatoms occur in glacial ice cores at an elevation of 5670 m a.s.l. in the Quelccaya Summit Dome ice field in the tropical Andes of Peru. The species composition of diatoms recovered from the ice indicates that most of the species originated from a dilute freshwater lake or wetland, and the excellent valve preservation suggests a local source rather than long-distance transport of dust from areas, such as the Southern Altiplano. Some taxa are common to all samples, while others are unique to individual samples. This variation probably reflects temporal changes in regional lacustrine diatom communities over the ~700 year span of the samples. The observations provide useful floristic information on diatom distribution in a relatively poorly documented region and also provide constraints on the size range of organisms that are transported by wind in similar high-elevation settings. The observations also suggest the potential for analysis of diatoms in future ice core studies, where shifts in species composition may provide evidence on local climate or environmental change that complements the other materials identified in the ice core record.
