Abstract

The circular distributions of plant modulars (branches, leaves) and endophagous herbivory (mines, galls) were investigated within the crowns of four dominant Fagaceae trees in a subtropical evergreen broadleaf forest at Jiulianshan National Nature Reserve, Jiangxi, China. The hypothesis is that more plant modulars and more endophagous herbivory should occur in the crown area perpendicular to the roads. Circular statistical techniques were used to verify new patterns of the impact of roads on plants and insects. The results confirmed that the roadside light environments had larger impacts on the circular distribution patterns of plant modulars than those of leaf herbivores. For herbivores, the impact of light was larger on mine distribution than on gall distribution. The branches of all four tree species were concentrated in the direction perpendicular to the roads. In the preferred direction, branches were longer and higher. More leaves, more mines, and more galls were found surrounding the preferred branch direction. In general, leaf miners and leaf gallers preferred leaves in the sun over those in the shade; however, leaf gallers had a lower degree of preference for sun than leaf miners. Different endphagous insects also showed clear interspecific differences in sun/shade leaf selection.

摘要

调查了中国江西九连山国家级自然保护区亚热带常绿阔叶林的四种壳斗科优势树种冠上的植物构件（枝、叶）和内食性昆虫取食状（潜道、虫瘿）的圆形分布。本文的假说是有更多的植物构件和内食性取食状分布于与小路相垂直的树冠区域。圆形分布统计技术用于证明小路对植物和昆虫影响的这种有趣的新格局。结果证实，光环境对植物构件圆形分布格局的影响要比对食叶昆虫的大；对于内食性昆虫而言，光环境对潜道分布的影响要比虫瘿分布的影响大。四个树种的枝条都集中分布在垂直于小路的方向上。在这首选方向上，枝条更长更高。有更多的叶片、潜道和虫瘿出现在枝条的首选方向上。潜叶昆虫和造瘿昆虫总体上更偏嗜阳叶而不是阴叶；但是，造瘿昆虫的这种偏嗜程度要小于潜叶昆虫。不同内食性昆虫的叶片选择存在明显的种间差异。
**Introduction**

Shade lessens the number of branches and leaves (Potter 1992; Huber and Stuefer 1997; Bartlett and Remphrey 1998; Lin et al. 2007; Lusk et al. 2008). Leaves in the sun and shade have different physical and chemical characteristics such as leaf size, leaf shape, leaf color, leaf trichome, nutrient content, secondary metabolites, and leaf temperature (Faeth et al. 1981; Rotheray 1987; Collinge and Louda 1988; Basset 1991; Faeth 1991a; Potter 1992; Moller 1995; Connor 2006; Pincebourde et al. 2007). The sun vs. shade distribution of natural enemies and endophytic fungi might affect the leaf miners and plant gallers (Fernandes and Price 1992; Wilson and Faeth 2001; Gange et al. 2002; Gange et al. 2007; Horvath and Benedek 2009). Thus, light will act directly or indirectly on the oviposition selection of leaf miners and leaf gallers (Connor 2006; Dai et al. 2011).

Different miners and gallers show different preference for leaves in the sun or shade on an individual plant. Some leaf miners, such as *Phyllonorycter maestingella*, *Stigmella hemargyrella*, *S. tiyrella*, *Cameraria* spp., and *Fenusa absens*, occur more on shaded leaves (Nielsen and Ejlersen 1977; Basset 1991; Faeth 1991a; Faeth 1991b; Smith and Altenhofer 2011); *Eriocraniella* spp., *Neurobathra strigifinitella*, *Dyseriocrania* spp., *Acrocercops* spp., *Bucculatrix cerina*, *Rhyaciaenus fagi*, *Stilbosis quadricustatella*, and *Phytomyza illicicola* are found more on leaves in the sun (Nielsen and Ejlersen 1977; Faeth et al. 1981; Kimmerer and Potter 1987; Simberloff and Stilling 1987; Horvath and Benedek 2009); *Cameraria hamadryadella* and *Eriocrania* spp. prefer equally sun and shade leaves (Brown et al. 1997; Riihimaki et al. 2003; Connor 2006); and *Brachys tessellatus* and *Cameraria ohridella* change their choices on leaves in the sun or shade in different seasons (Turnbow and Franklin 1981; Horvath and Benedek 2009). For plant gallers, some prefer leaves in the sun while others show no preference between leaves in the sun and leaves in the shade (Nielsen and Ejlersen 1977; Basset 1991; Leite et al. 2009).

The studies mentioned above divided a plant crown into two parts, those in the sun and those in the shade. However, branches, leaves, and herbivory in different crown microhabitat area will experience a gradient variation of light levels. If the crown is projected as a circle on a plane, then circular statistical techniques can be adopted to study directional patterns such as crown displacement (Ackerly and Bazzaz 1995; Aradottir et al. 1997; Rouvinen and Kuuluvainen 1997; Muth and Bazzaz 2003; Tarara et al. 2005; Getzin and Wiegand 2007; Schröter et al. 2011), branching and leafing characteristics (Neufeld et al. 1988; Hollinger 1989; Doruska and Burkhart 1995; Gielen et al. 2002; Trincado 2006), and herbivory (Alonso 1997; Bonebrake et al. 2010).

After preliminary investigation, the number of branches, number of leaves, number of leaf mines per leaf, and number of leaf galls per leaf seemed to be different in different tree crown areas. Moreover, plant modulars and leaf herbivores were concentrated in the crown area closer to the roads. In order to show the sophisticated impacts of roadside light environments on plants and insects, circular statistics were adopted to quantify and verify distribution patterns around tree crowns. The following two questions were addressed: (1) Is the density of leaf miners and leaf gallers higher in some specific tree crown areas? (2) Are there interspecific differences in circular distribution patterns...
among leaf miner species and leaf galler species?

**Materials and Methods**

**Study site**

The 134-km² Jiulianshan National Natural Reserve is located in the south of Jiangxi Province, China (24° 29′ 18″–24° 38′ 55″ N, 114° 22′ 50″–114° 31′ 32″ E). It is a mountainous area with an altitude range from 280 to 1,434 m a.s.l. The climate is subtropical, with a mean annual precipitation of 2,156 mm that occurs mainly in the wet season, from February to September. The mean monthly temperature varies from 6.8° C (January) to 24.4° C (July). Major vegetation types include subtropical evergreen broadleaf forest, low hill coniferous forest, bamboo forest, montane dwarf forest, and montane grassland (Liu et al. 2002).

**Data collection**

In July 2011, leaf herbivory was examined within the crowns of half-shaded understory trees beside small forest roads (Figure 1). Three *Castanopsis carlesii* (Hemsl.) Hayata (Fagales: Fagaceae) individuals with 50 branches, four *C. fabri* Hance with 90 branches, five *C. fargesii* Franch. with 84 branches, and six *Cyclobalanopsis glauca* (Thunb.) Oerst. with 81 branches were sampled. Leaves from the outermost 0.5 m sections of the branches (including large branches and pseudo-branches) were collected and counted for the number of leaves, leaf mines, and leaf galls. The types of leaf mines and leaf galls were decided according to their shape, position, and color (Appendix 1, 2) (Hering 1957; Csóka 1997, 2003; Redfern 2011). The fresh leaf miners were collected from time to time and reared in the laboratory, and photos of leaf miners were sent to taxonomists for identification. The density of one leaf mine type or one leaf gall type was measured as the number of leaf mines or leaf galls per leaf in each branch. Road directions were pointing from 180° to 0°. The whole crown can be divided into two sides, sun side (0–180°) and shade side (180–360°). Relative azimuths α of each large branch to the road direction were also measured. Branch length was measured from the base of branch to the farthest leaf. Branch height was the height of branch base. The base of one pseudo-branch was put at the base of the large branch where the longer small branch belonged (Figure 1).

**Statistical analysis**

Data from different individuals of the same tree species were pooled together. Relative azimuths α are angular data. Such angular measurements could be treated as points on one circle. Then, circular statistics were used to compute the mean vector. The mean vector has two properties: mean angle μ and its length r. r falls in the interval [0, 1]. r is close to 1 for the data highly concentrated around one direction, and close to 0 for widely dispersed data. Rayleigh’s uniformity test was performed to assess the significance of r (Zar 1999; Jammalamadaka and Sengupta 2001; Dai et al. 2007). V-test was used to test whether circular data α have a mean of 90°. A circular histogram was plotted for α, and a circle was drawn on the histogram to show the level of the Rayleigh critical value (p = 0.05 here). If the r vector extends beyond the circle, then the Rayleigh test is significant (Figure 2).

For the circular distribution of plant modulars and leaf herbivores, vector pairs were defined to consist of relative azimuths α as a circular variable and one other parameter as a weight variable. The latter could be branch length, branch height, number of leaves per branch, number of leaf mines per leaf, number of leaf
galls per leaf, etc. Weighted mean vector (WMV) and its length $r$ (scaled 0–1) were obtained. Moore’s modified Rayleigh test was used to test the significance of $r$ here (Zar 1999).

All statistical analyses were conducted in Oriana version 4.00 (Kovach Computing Services, www.kovcomp.co.uk/oriana).

Results

Circular distribution of branches and leaves

Mean relative azimuth $\mu$ of branch direction was 100.5° for *C. carlesii*, 107.7° for *C. fabri*, 89.3° for *C. fargesii*, and 72.7° for *C. glauca* (Figure 2). The corresponding $r$ was 0.528, 0.491, 0.423, and 0.637 respectively. Relative azimuths $\alpha$ were not evenly distributed in all directions (Rayleigh tests, $Z = 13.941$, $n = 50$, $p < 0.01$; $Z = 21.681$, $n = 90$, $p < 0.01$; $Z = 15.038$, $n = 84$, $p < 0.01$; and $Z = 32.829$, $n = 81$, $p < 0.01$ for *C. carlesii*, *C. fabri*, *C. fargesii*, and *C. glauca* respectively). Moreover, $\alpha$ concentrated around 90° (V-tests, $V = 0.519$, $n = 50$, $p < 0.01$; $V = 0.468$, $n = 90$, $p < 0.01$; $V = 0.423$, $n = 84$, $p < 0.01$; and $V = 0.608$, $n = 81$, $p < 0.01$ for *C. carlesii*, *C. fabri*, *C. fargesii*, and *C. glauca* respectively).
The WMV of relative azimuths weighted by branch length, by branch height, and by number of leaves per branch were all between 90 ± 30° for four tree species. Moore’s modified Rayleigh test showed that all WMVs were significantly concentrated (p < 0.01) and all r-values were larger than 0.167 (Table 1).

**Circular distribution of leaf miners and leaf gallers**

The composition of leaf miners and leaf gallers was different between the three *Castanopsis* trees and the *Cyclobalanopsis* tree (Table 2).

The WMVs of relative azimuths weighted by the density of most leaf mine types (FLM01, FLM05, FLM07, FLM09) and by the density of all leaf mines were all between 90 ± 30° for all four tree species. The WMVs of FLM02 and FLM03 were outside 90 ± 30° but within the range of 0 to 180° (sun side). The WMV of FLM04 was within the sun side but not always between 90 ± 30°. Moore’s modified Rayleigh test indicated that all WMVs were significantly concentrated (p < 0.01) while all r-values were between 0.018 and 0.116 (Table 2).

The WMVs of relative azimuths weighted by the density of each leaf gall type were outside 90 ± 30° but within 0–180° for three *Castanopsis* species. The WMVs of relative azimuths weighted by leaf gall types were different from zero, where ** indicates p < 0.01. No observation or too few observations (n < 4).
within 0–180° (sun side) but not always between 90 ± 30° for *C. glauca*. For the leaf gall types, the WMVs of FLG01, FLG04, FLG07, FLG08, FLG09, and FLG12 were outside 90 ± 30°, while the WMVs of FLG02, FLG03, and FLG05 were between 90 ± 30°. For *C. glauca*, the WMV variations were very evident. The WMVs of relative azimuths weighted by the density of all leaf galls in four trees were generally away from 90°. Moore’s modified Rayleigh test indicated that all WMVs were significantly concentrated (*p* < 0.01) while all *r*-values were between 0.014 and 0.061 (Table 3).

**Discussion**

The length of WMVs (*r*) could be ordered as follows: *r* (branch direction) > *r* (branch length) > *r* (branch height) or *r* (No. leaves per branch) > *r* (mine density) > *r* (gall density) (Tables 1–3). It seems that light environment had a larger impact on the circular distribution of plant modulars than on that of leaf herbivores. For herbivores, light impacts were larger on mine distribution than on gall distribution. The branches of all four tree species were concentrated in the direction perpendicular to the roads (Figure 2). In the preferred direction, branches were longer and higher. There were also more leaves, mines, and galls around the preferred direction of branches (Tables 1–3).

Generally, leaf miners and leaf gallers preferred sun leaves rather than shade leaves. However, leaf gallers had a lower degree of preference to sun than leaf miners. The sun vs. shade distribution patterns were consistent with some studies (Faeth et al. 1981; Hartman 1984; Fernandes and Price 1992), but not with others (Basset 1991; Dudt and Shure 1994; Fernandes et al. 2004). Generally, leaf mines were found on the upper side of leaves while leaf galls were on the lower side of leaves, which might explain their differences in sun-shade pattern.

Different endophagous insects showed clear interspecific differences in leaf selection. For example, the mines of Rhynchaeninae weevils (FLM07) were mostly found in leaves fully exposed to the sun, which is consistent with other leaf-mining beetles (Nielsen and Ejlersen 1977; Turnbow and Franklin 1981; Waddell and Mousseau 1996); the mines of *Stigmella* spp. Goze (Lepidoptera: Nepticulidae) (FLM01 and FLM03) were also more prevalent in leaves in the sun, which is contrary to the previous observations (Nielsen and Ejlersen 1977; van Nieuwerken 2006). The mines of *Phyllonorycter* spp (FLM02) were not concentrated in fully-sun leaves, which is the same as other *Phyllonorycter* (Nielsen and Ejlersen 1977). The mines of *Acrocercops* spp (FLM04) were generally more in the sun side, which is same as other *Acrocercops* on Fagaceae trees (Faeth et al. 1981). The mines of *Tischeria* spp (FLM05) also preferred leaves in the sun, which is different than other *Tischeria* (Connor 2006).

Light intensity, light quality, and light time are different in different crown areas. The sun vs. shade leaves in our study were identified according to the road, not to the absolute south or north compass direction (Basset 1991). From this view, more plant modulars and a higher density of herbivorous insects occurred in the crown area perpendicular to the roads, indicating that high light intensity and long light hours are beneficial factors for these organisms. Compared to the traditional sun-shade analysis, circular analysis could provide a more detailed picture of light impact on plants and insects. Our next study is to measure circular distribution of light parameters and leaf chemical content around tree
crowns and to connect the two investigations to discover leaf selection mechanisms of leaf-mining insects. Moreover, the concentration of leaf-feeding insects in specific areas might help control them precisely, for example, to release natural enemies or to apply pesticides only in the target area.
