ABSTRACT: The C120 Magnum trap, equipped with a 66 × 69 mm pan trigger, which favored double strikes in the neck and thorax regions, successfully killed nine of nine wild mink (*Mustela vison*) in simulated natural conditions. Average times to loss of consciousness and heartbeat were estimated at <72 (±24) sec and 158 (±48) sec, respectively, after firing of the trap. This study confirmed that the C120 Magnum trap can be expected to render >79% of all captured mink unconscious in ≤3 min ($P < 0.05$). This is the first mink kill trap to meet the requisites of the Canadian General Standards Board regarding killing traps.

Key words: C120 Magnum quick-kill trap, humane trapping, mink, *Mustela vison*, rotating-jaw trap, experimental study.

INTRODUCTION

Because of the perceived cruelty associated with use of the leghold trap, the wildlife management authorities of three Canadian provinces have recently prohibited the use of conventional leghold traps in land sets for capturing most furbearers (Barrett et al., 1988). In most regions, the commercially available rotating-jaw Conibear® (Woodstream Corporation, Lititz, Pennsylvania 17543, USA) has been promoted as an alternative means for trapping small furbearers. The Conibear 120® (C120) is marketed as a quick-kill trap for mink (*Mustela vison*) and its use is recommended in trapping and conservation manuals (Canadian Trappers Federation, 1984; Alberta Vocational Centre, 1987). However, the standard C120, equipped with a two-prong trigger, does not consistently strike mink in vital areas (Cook et al., 1973; Voigt, 1974) and its impact and clamping energies are lower than those recommended by the Canadian General Standards Board (1984) for marten (*Martes americana*) and mink (Cook and Proulx, 1989).

Proulx et al. (1989a) developed the C120 Magnum trap (the researchers did not ac-quire a registered trademark so that the trap can be produced by any manufacturer) which rated higher than the Canadian General Standards Board's (1984) kill threshold values (minimum striking and clamping forces) for marten and mink. This trap quickly killed marten struck in the head-neck region (Proulx et al., 1989a), but did not effectively kill mink struck in the neck (Proulx and Barrett 1989). This may be due to the greater cervical musculature and stronger bones of the mink. However, the work with marten (Proulx et al., 1989a) demonstrated that double strikes, where animals were simultaneously struck in the head-neck and thorax regions by the distal and proximal rotating-jaws, respectively, produced consistent and rapid unconsciousness. Double strikes damaged the central nervous system or impeded the respiratory functions of the animals (Proulx et al., 1989a). Given similar strike locations, the C120 Magnum trap could have the potential to quickly kill mink.

The objectives of this study were (1) to develop a trigger system for the C120 Magnum trap that will ensure consistent double strikes in the head-neck and thorax regions of mink, under simulated natural
FIGURE 1.   Diagram of the Conibear 120 Magnum trap with four clamping bars.

conditions; and (2) to evaluate the potential of the C120 Magnum to quickly kill mink which received a double strike.

MATERIAL AND METHODS

The study was conducted in a 2.2 ha forested compound at the Alberta Environmental Centre (Vegreville, Alberta, Canada T0B 4L0). Wild-

caught mink were individually introduced in 12.2 × 5.2 × 4.4 m test enclosures and were allowed a minimum of 3 days to acclimate to simulated natural conditions before any tests were conducted. Enclosures were kept under surveillance with two remote control Panasonic® WV 1854 video-cameras (Avicom Industrial Communications, Edmonton, Alberta, Canada T5S 1G7) equipped with a Comiscar® 15–180 mm F1.9 lens (Avicom Industrial Communications, Edmonton, Alberta, Canada, T5S 1G7) and a high efficiency 500 watt infrared (invisible to animal eyes) light illuminator (Avicom Industrial Communications). Personnel observed the video monitors in a laboratory building approximately 125 m from the enclosures. Proulx et al. (1989b) described the facilities, equipment and husbandry procedures.

The C120 Magnum traps used in this study were similar to those of Proulx et al. (1989a). However, they had four clamping bars instead of two to reinforce the trap's metal frames (Fig. 1). Traps were set in a ground cubby box (Fig. 2) (Proulx et al., 1989b) similar to the one used by trappers (Alberta Vocational Centre, 1987).

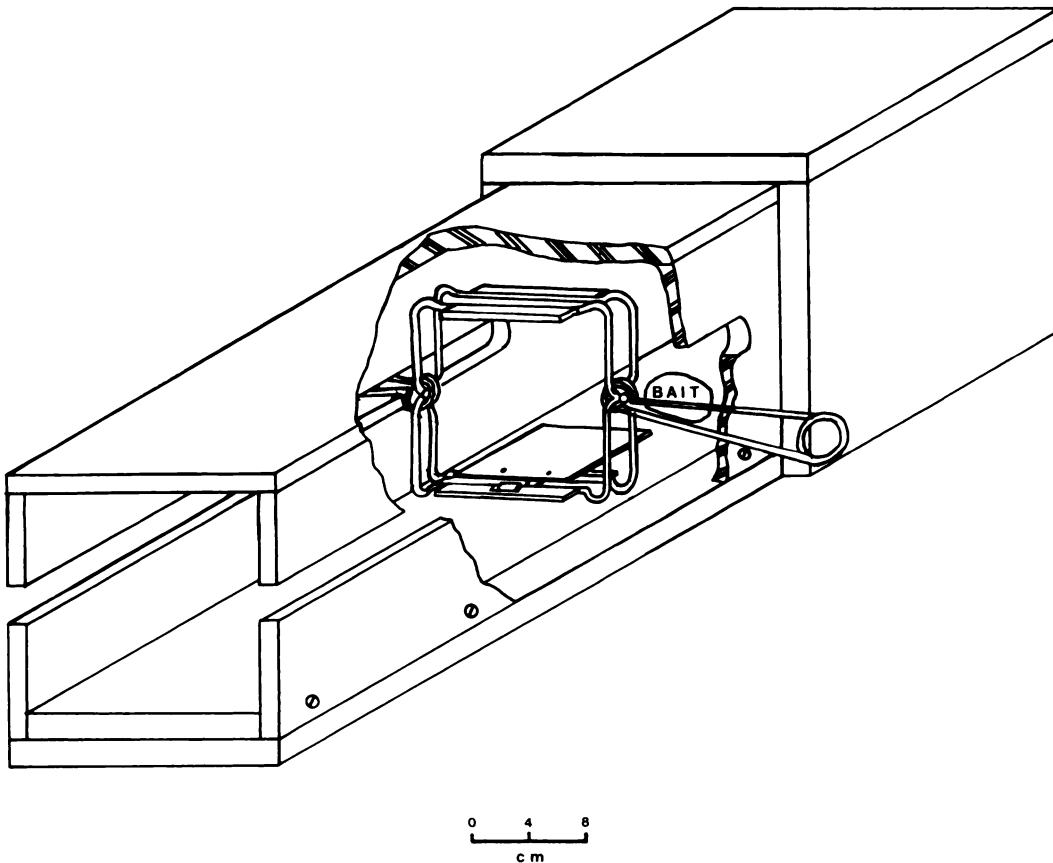

FIGURE 2.   C120 Magnum with 66 × 69 mm pan trigger in cubby set.

They were equipped with pan triggers which operated on a cam-lever principle (Fig. 3). A bait consisting of ranch mink feed was tied down 10 cm behind the center of the trap.

A test sequence was designed to minimize pain and suffering of animals, to ensure efficient use of mink, and to thoroughly evaluate the killing potential of traps. It consisted of approach tests, pre-selection tests, kill tests, and performance confirmation tests (Proulx et al., 1989a, b). In order to qualify for each category of testing, traps had to pass the previous category.

In approach tests, naive animals that presumably had never encountered a Conibear trap[e] were allowed to approach C120 Magnum traps wired in the set position so that the traps could be triggered but not close completely and injure the animals. The strike locations were determined on video monitors by projecting the arc movement of the striking bars on the animals at firing time. These tests were used to develop a trigger system that would ensure that mink would be consistently struck in both head-neck and thorax regions. A trigger system was judged acceptable if animals were successfully positioned in five or more of six approaches. Two series of six approaches were conducted with a 65 × 100 mm and a 81 × 91 mm pan triggers. However, during the approach tests, it was noticed that mink could accidentally fire the trap before entering it, by stepping on the anterior part of the part of the pan which faced the cubby entrance. The pan was subsequently shortened to a 69 mm length so that it did not extend past the proximal striking jaw (Fig. 2).

In the past, a trap was judged "humane" when it rendered three of three animals irreversibly unconscious within 3 min (Federal Provincial Committee for Humane Trapping, 1981). However, Proulx et al. (1989a, b) considered that a sample size of three was unacceptably low to reach a satisfactory conclusion about the true effectiveness of a trap. They suggested that the assessment of the killing ability of a trap should involve more kill tests and that a trap should be considered "humane" if it has the potential to kill >79% of all target animals in an actual field situation. Such a performance level is considered to be very high and no commercial trapping device has been shown to meet it (Proulx and Barrett, 1989).

This study followed previous kill test protocols (Proulx et al., 1989a, b). The killing potential of the C120 Magnum trap was first assessed in pre-selection tests with six traps and six mink (those used in the approach tests with the 65 × 100 mm pan trigger) immobilized with ketamine hydrochloride (10–20 mg/kg; Austin Laboratories, Joliette, Quebec, Canada J6E 3Z1).

FIGURE 3.   Diagram of the 66 × 69 mm pan trigger of the Conibear 120 Magnum trap.

This preliminary assessment allowed the researchers to determine if the C120 Magnum generated sufficient impact and clamping energies to quickly kill mink, without causing suffering to the animals. If a trapping device would not effectively kill immobilized animals, it is unlikely that it would do so with active animals that are aware of what is happening to them and would "fight" the trap (Proulx et al., 1989b). The C120 Magnum would pass the pre-selection tests if it rendered at least five of six animals irreversibly unconscious in ≤3 min (Canadian General Standards Board, 1984). Irreversible unconsciousness was diagnosed by loss of corneal and palpebral reflexes (Walker, 1979; Horton, 1980; Rowsell et al., 1981) with inevitable subsidence into death (loss of cardiac activity determined with a stethoscope). The immobilized animals were situated in traps in a position that duplicated placement in the approach tests (Proulx et al., 1989b), and the presence of their eye reflexes was confirmed before firing the trap.

Upon success at the pre-selection test level, a second assessment of the potential effectiveness of the C120 Magnum was carried out in six kill tests with each trap equipped with a 66 × 69 mm pan trigger and placed in a cubby set. The C120 Magnum would be considered potentially effective if it successfully rendered at least five of six animals irreversibly unconscious in ≤3 min.

Thereafter, the C120 Magnum was evaluated in additional kill tests, termed performance confirmation tests, in order to be 95% confident that it could be expected to effectively kill >79% of all captured mink (Proulx et al., 1989a). On the basis of the normal approximation to the binomial distribution (Fleiss, 1981), the C120 Magnum would be expected to effectively kill >79% of mink on traplines if, during the kill and performance confirmation tests, it rendered nine of

nine (0 failure), or 13 of 14 (one failure), or 18 of 20 (two failures) mink irreversibly unconscious in ≤3 min (Proulx et al., 1989a).

The kill tests were conducted from October 1987 to February 1988. Upon firing of the trap, researchers ran to the test enclosure to monitor the state of consciousness of the animals. Animals were necropsied by a veterinary pathologist at the Alberta Environmental Centre (Vegreville, Alberta, Canada T0B 4L0). The pelts were examined for damage before and after skinning the animals.

Animal husbandry and research procedures were conducted in accordance with the guidelines of the Canadian Council on Animal Care (1984). Protocols for the kill tests were referred to the Council for their review prior to implementation.

RESULTS

All approach tests resulted in double strikes in the head-neck and thorax regions.

In pre-selection tests, average times to loss of consciousness and heartbeat were 60 (±63) sec and 225 (±66) sec, respectively (Table 1). Damage to the central nervous system was apparent in two cases. Compression and/or laceration of muscles and congestion of lungs were common in all kills (Table 1). The trap successfully passed (six of six) the pre-selection tests.

All the kill and performance confirmation tests were successful (Table 2). In the majority (78%) of cases, corneal/palpebral reflexes had been lost prior to arrival of the observers and average time to loss of consciousness was <72 (±24) seconds (Table 2). Heartbeat was lost, on average, 158 (±48) seconds after firing of the trap. The central nervous system was not damaged. Fractures were recorded in four animals

and were mainly limited to vertebral spinal processes. Major trauma consisting of cardiac tamponade, hemothorax and pulmonary hemorrhage were found in a few mink (Table 2).

This study confirmed that the C120 Magnum equipped with a 66 × 69 mm can be expected to render >79% of captured mink unconscious in ≤3 min ($P <$ 0.05).

DISCUSSION

The C120 Magnum with pan trigger is the first mink kill trap to meet the requisites of the Canadian General Standards Board (1984). Because of its longer springs, the C120 Magnum is easier to set than the C120®. It is a safe trap to work with when the springs are equipped with safety hooks identical to those of the Conibear 220® trap

(Woodstream Corporation) and when a Conibear Safety Gripper® (Woodstream Corporation) is used to hold the jaws together while setting the trap. Although the C120 Magnum is more powerful than the C120® (Proulx et al., 1989a), it did not damage mink pelts. The efficacy of this trap under controlled conditions now warrants field studies to compare its capture efficiency to that of commercial devices.

This study, and the work of Proulx et al. (1989a, b), illustrates that it is possible to increase the killing potential of traps. However, it also points out that caution should be exercised in expressing general statements about types of strikes. In the past, double strikes were not acceptable mainly because such strikes had never been critically evaluated. Some of the preliminary work on double strikes involved only a few animals and inconsistent strike locations (Novak, 1981) or trap designs which were much less powerful than the C120 Magnum (Gilbert, 1981). Research using animals in simulated natural environments is necessary to confirm the killing potential of trap whose energies meet or exceed the kill thresholds recommended by the Canadian General Standards Board (1984). These animal studies lead to the establishment of relationships between strike location and time to unconsciousness, and the accumulation of background data necessary to interpret the killing performances of traps on working traplines.
