ABSTRACT—Massive accumulation of glycogen in the follicles of *Scotophilus heathi* during the period of delayed ovulation was noticed. The follicles which survive for prolonged periods are morphologically specialized. The accumulation of glycogen was noticed in the granulosa cells. The egg cytoplasm, thecal cells and interstitial cells were almost devoid of glycogen. The first sign of a glycogen deposit in the ovary was noticed during the recrudescence phase (October) in late pre-antral follicles. Most of the morphologically healthy late pre-antral and antral follicles showed a positive reaction with PAS and Best carmine from October to early February. Morphologically atretic follicles showed only a mild glycogen accumulation. Little or no glycogen accumulation was noticed in some of the healthy late-antral follicles before ovulation during late February and early March. HCG-induced antral follicles during quiescence also did not show any accumulation of glycogen. The study suggests that glycogen laden follicles are not suitable for ovulation and may be the reason for the occurrence of delayed ovulation in *S. heathi*.

INTRODUCTION

The remarkable longevity of follicle and prolonged delay in ovulation are unique features in reproductive cycle of hibernating temperate zone vespertilionid bats (Oxberry, 1979). The follicles which survive for prolonged period have been shown to be morphologically specialized, such as hypertrophy and hyperplasia of the granulosa cells. These hypertrophied granulosa cells show heavy accumulation of glycogen which is transferred to the oocyte by follicle cell processes. These modifications are considered to be an adaptation to meet the energy requirements to the ovarian follicle complex during winter dormancy (Wimsatt and Parks, 1966). The specialized ovarian follicles, analogous to the described in temperate zone vespertilionids, are also found in tropical vespertilionids; e.g., *Pipistrellus ceylonicus chrysotrich*, *Pipistrellus minullus minullus* and *Pipistrellus dormeri* (Gopalakrishna et al., 1974). Whether such chemically and morphologically specialized follicle is an adaptation related to period of delayed ovulation or prolonged survival of Graafian follicle is not clearly known. *Scotophilus heathi*, a tropical vespertilionid bat, has been shown to exhibit the phenomenon of delayed ovulation and heavy accumulation of glycogen in follicles, which are about to ovulate (Krishna and Dominic, 1980; Krishna and Singh, 1992). The present investigation was therefore undertaken in *S. heathi* to elucidate the following: whether follicles in all stages of growth or only Graafian follicle exhibit glycogen accumulation; whether glycogen deposit in the ovarian follicle occurred only during the period of delayed ovulation or throughout the year. An additional study was performed to find out whether antral follicles induced by exogenous hCG during non-breeding phase also accumulate glycogen.

MATERIALS AND METHODS

Bats were trapped alive in every calendar month in the Banaras Hindu University campus and adjacent area. Animals were sacrificed as soon as they were brought to the laboratory. Bats were maintained in small cages with free access to water in a room at 20-25°C and 14 hr light: 10 hr dark schedule. Ovaries were dissected out, fixed in alcoholic Bouin's or calcium formal, embedded in paraffin wax, and serially sectioned at 5 µm. The section were stained with periodic acid Schiff's (PAS) reagent, alcian blue and Best carmine with and without diastase treatment (Pearse, 1968). Follicles were classified as shown in Table 1 and Fig. 1-4.

HCG treatment

HCG (10 IU) in saline were injected as single ip dose after 24 hr of capture. The animal were sacrificed 48 hr after the injection. The ovaries were dissected out and proceed for PAS staining as described earlier.

RESULTS

Morphological features of the follicle during delayed ovulation

*S. heathi* exhibits a sharply defined annual breeding season. Both ovaries contained numbers of primordial and early pre-antral follicles throughout the year. The first sign of recrudescence of the ovary was noticed in females collected during late September and early October. Large numbers of growing follicles in late pre-antral stage were noticed at this stage (Fig. 1). In November the ovary contains several early...

and late antral follicles (Fig. 2). During late January and February, two to four morphologically healthy Graafian follicles (late-antral) were present in each ovary (Fig. 3). Some follicles with distinct morphological sign of atresia were also present in the ovary (Fig. 5). Ovulation occurs during the first week of March. During December to early March, granulosa cells of late-antral follicles underwent hypertrophy resulting in the reduction of the antral cavities to a few small spaces (Fig. 3). The pronounced hypertrophy of the discus proligerus (Fig. 4) and associated follicle cells was a prominent and characteristic feature of the late-antral follicles. The glycogen accumulation was prominent in Graafian follicles having hypertrophied granulosa cells. The intensity of accumulation was much greater in granulosa cells having large frothy appearance as compared with follicles having smaller granulosa cells (Fig. 6).

Histochemical observations

The ovarian sections treated with PAS or Best carmine showed intense positive reaction for glycogen in the antrum and in the cytoplasm of granulosa cells (Table 2, Fig. 7). The egg cytoplasm, thecal cells and interstitial cells, however, showed a negative reaction for glycogen (Fig. 7). The follicle cells also exhibited a positive reaction with alcin blue indicating the presence of acid mucopolysaccharides.

In order to find out whether follicles in all stages or only Graafian follicles exhibit glycogen accumulation, and whether deposits in the ovarian follicles occurred only during the period of delayed ovulation or year round, ovarian sections from animal collected throughout the year were stained with PAS. Both pre-antral and antral follicles showed glycogen accumulation. The first sign of glycogen deposits was noticed in late pre-antral follicle in the ovaries of bat collected during October. All healthy late pre-antral and antral follicles in the ovaries of bats collected from October to February showed PAS-positive reaction (Table 3). The morphologically atretic follicles exhibited only a mild or negative reaction (Fig. 7). The intensity of PAS reaction showed a gradual increase from late pre-antral to antral follicles. The reaction was not detectable in early pre-antral follicles. The pattern of glycogen accumulation changes just before ovulation during late February and early March. During this period, only late antral follicles were showing mild PAS positive reaction, while most of the pre-antral and a few of the antral follicles did not show any PAS-positive reaction (Table 3, Fig. 8). Neither the early pre-antral follicle (except the zona pellucida) nor other parts of the ovary showed a PAS positive reaction during the period from late March to September. During this period the ovary contains only early pre-antral follicles. The corpus luteum showed no reaction with PAS.

HCG-treatment

Since only early pre-antral follicles were found in the ovary during the period from April to August, the effect of season on glycogen deposition in the antral follicles could not be determined in normal female bats. Treatment of hCG in female bat during this phase causes several changes in the ovary such as intense hyperaemia, hypertrophy of interstitial cells and appearance of numerous late pre-antral and antral follicles. The ovarian section of these hCG treated females did not show any glycogen accumulation in the follicles.

**DISCUSSION**

The peculiarities in the structure of the antral follicles as noticed in *S. heathi* are comparable to those described in other vespertilionids (Oxberry, 1979; Dominic and Krishna, 1989). These follicles are characterised by a reduced antral cavity and ovum being surrounded by a large discus proligerus, the cells of which are considerably hypertrophied and vesicular. These peculiarities in the antral follicles may be because of the occurrence of delayed ovulation and prolonged survival of the late antral follicle in *S. heathi* (Krishna and Singh, 1992).
Glycogen Accumulation in Ovarian Follicle
In *S. heathi* glycogen accumulation was noticed in most of the morphologically healthy late pre-antral and antral follicles found during the period from September to February (Table 3). Folicie showing morphological sign of atresia had only mild accumulation of glycogen. This is the period when the ovarian recrudescence and delayed ovulation is reported in this species (Krishna and Singh, 1992). It is interesting to note that glycogen accumulation was much greater in antral follicles having hypertrophied granulosa cells. Before ovulation, during the late February and early March only a mild PAS positive reaction was noticed in some of the antral follicles. While most of the pre-antral and some of the antral follicle showed a negative PAS reaction in the granulosal cells. The ovaries of bats collected during late March to August failed to demonstrate any accumulation of glycogen in pre-antral follicles. Glycogen accumulation was also not noticed in both pre-antral and antral follicles in the ovaries of hCG treated bats during this period. These observations indicate that the period of glycogen accumulation in the follicle coincides with the period of prolonged survival of antral follicles and delayed ovulation in *S. heathi*. Glycogen accumulation in most of the follicles decreases drastically before ovulation.

Polysaccharides (glycogen) as a energy source for follicle cells have been regarded as an important aspect of the prolonged survival of the Graafian follicle during hibernation (Oxberry, 1979, Son et al., 1987). The ultrastructural studies of Wimsatt and Parks (1966) on the Graafian follicle of *Myotis lucifugus* have shown that glycogen stored in the granulosa cells is transferred to the oocyte by follicle cell processes that pass through the zona and penetrate the oocyte surface. These authors consider these modifications as an adaptation to meet the energy requirements of the ovum-follicle complex during winter dormancy in the temperate zone vespertilionid bats. The present studies in *S. heathi*, however, have failed to demonstrate accumulation of glycogen in the oocyte. Since *S. heathi* is a tropical species and does not undergo prolonged hibernation, it is doubtful whether the accumulation of glycogen in the follicle cells has any adaptive value to meet the energy requirement of the ovum follicle complex in this species. Furthermore in *S. heathi*, glycogen accumulation during the period from October to early February is not only found in surviving antral follicles, but in all the follicles beyond early pre-antral stage of development.

Thus, it is reasonable to assume that in *S. heathi*, glycogen accumulation in the follicles may not be an adaptation for prolonged survival of the follicle. Accumulation of glycogen in the follicles in *S. heathi* was found to be seasonal. The follicles recruited during the period from October to early February showed heavy accumulation of glycogen. Previous attempts to induce ovulation in these bats during this period was unsuccessful (Singh and Krishna, 1992). This study thus suggests that antral follicles present in the ovary of *S. heathi* during the period from October to early February may not be suitable for ovulation, this could be because of the presence of Wimsatt and Parks (1966) on the Graafian follicle of Myotis lucifugus.
Glycogen Accumulation in Ovarian Follicle

of glycogen in the antral follicles. Appearance of glycogen in the cumulus oophorus is generally associated with early sign of follicular atresia (Guraya, 1985). Recent study from our laboratory demonstrated very high rate of androstenedione production from the ovary of *S. heathi* during the period of delayed ovulation (Abhilasha and Krishna, 1996). It is well known that high ovarian androgen production causes number of intra-ovarian effects, which include inhibition of follicular growth and ovulation and enhanced rate of follicular atresia (Billiar et al., 1985; Faiman et al., 1988). This observation further suggest that glycogen-laden follicles present in the ovary of *S. heathi* during the period of delayed ovulation may not be physiologically healthy, although morphologically they do not exhibit classical sign of atresia. This might be the reason for the occurrence of delayed ovulation in *S. heathi*. Interestingly, the morphologically atretic follicles showed depleted glycogen accumulations. This observation suggest that as long as follicles contain sufficient glycogen they remain morphologically healthy and retained in the ovary for prolonged period. Before ovulation, most of the pre-antral and some of the antral healthy follicles were found without any accumulation of glycogen. This is because in *S. heathi*, a second wave of follicular growth, resulting in a fresh recruitment of antral follicles occurs in late February (Krishna and Singh, 1992). This indicate that glycogen accumulation does not occur in the follicles recruited after mid February, which most likely ovulate during early March. The underlying factor(s) which induce the accumulation of glycogen in most of the follicles during the period from October to early February and the factor(s) which later prevents the accumulation of glycogen within follicles just before ovulation in *S. heathi* is obscure.
